## THE ALLOTROPY AND SOLUBILITIES IN WATER OF AMMONIUM BROMIDE.

BY ALEXANDER SMITH AND HERBERT E. EASTLACK.

Received May 8, 1916.

### Introductory.

Wallace,<sup>1</sup> using cooling-curve, dilatometric, and optical methods, observed that ammonium chloride and ammonium bromide undergo enantiotropic transformation at  $159^{\circ}$  and  $109^{\circ}$ , respectively. The chloride has recently been more carefully studied by Scheffer.<sup>2</sup> He finds from heating and cooling curves that the transformation takes place between the limits  $187^{\circ}$  (heating) and  $174^{\circ}$  (cooling). Determination of the solubility of ammonium chloride in water from  $160^{\circ}$  to  $205^{\circ}$  gave two curves intersecting at  $184.6^{\circ}$ , the transition temperature.

Before Scheffer's paper appeared, we had obtained similar results with the chloride from heating and cooling curves. The same method applied to the bromide had shown the transformation to take place at  $143\text{--}144^{\circ}$  on heating, while for the cooling curves the temperature varied from  $119^{\circ}$  down to about  $107^{\circ}$ . An experiment in which the thermometer and salt were sealed in a glass tube with a small amount of water (only the vapor phase, however, being in contact with the bromide) showed a

<sup>1</sup> *Centralblatt Min. Geol. u. Paläontol.*, 1910, 33.

<sup>2</sup> *Proc. Akad. Wetenschappen*, 18, 446 (1915); *C. A.*, 10, 411 (1916).

change on cooling at about  $130^{\circ}$ . The transition temperature for the bromide thus lay between the limits  $130^{\circ}$  and  $143^{\circ}$ . The low temperature reported by Wallace may be due either to an error in the calibration of his thermocouple, or more probably to supercooling, since the transformation in both cases is very sluggish.

The more exact determination of these two transition temperatures was in progress when Scheffer's paper came to our notice. In as much as his work had fixed with sufficient accuracy the transition point of the chloride, we completed only the determination of the transition temperature of the bromide, by measuring the solubilities of the salt in water over a temperature range sufficient to include the transition point.

In making the solubility determinations from  $100$  to  $170^{\circ}$ , it was observed that our curve was not a continuation of the one given by the solubility tables, all of which take their data from an article by Eder.<sup>1</sup> Consequently the determinations were carried on down to  $0^{\circ}$  in order to give a complete solubility curve for ammonium bromide.

### The Experimental Method.

The sealed tube method, which has been widely used in the investigation

Fig. 1.—(Linear dimensions = actual size.)

of freezing point or solubility curves of various systems<sup>2</sup> where one of the components has a high vapor pressure, was the only method practicable for the present investigation.

A piece of soft glass tubing about 1 cm. in diameter was constricted and closed at one end (Fig. 1a) forming a bulb of about 1 cc. capacity. The volume of the bulb, required in calculating the weight of water in the vapor phase, was determined by weighing the tube empty and filled to the constriction with water. After the tube was carefully dried a small amount of ammonium bromide, which has been recrystallized from distilled water, sublimed *in vacuo* and dried at  $110^{\circ}$ , was introduced into the bulb and the tube was again weighed. An approximate weight of distilled water was then added, the bulb sealed off at the constriction and finally the two parts were weighed. A short length of glass rod was then fused on to the bulb (Fig. 1b) and

served to support the bulb in the bath.

"Crisco" cooking oil, well stirred in a large beaker, was employed as a bath. A Bunsen burner was regulated to maintain a temperature one or two degrees below that desired, and the final temperature was obtained from an elongated electric light bulb partially immersed in the bath. With a switch to operate this light, the temperature of the bath could easily be maintained constant, to within a few hundredths of a degree, at any desired point from that of the room to about  $200^{\circ}$ . The mercury thermometer used was a standard instrument, graduated to  $1/5^{\circ} C.$ , and calibrated by the Reichsanstalt. A correction was applied for the exposed stem.

The saturation temperature was taken as the mean of determinations made with rising and falling temperatures.<sup>1</sup> For the former, the temperature was first raised sufficiently to completely dissolve the ammonium bromide. By sudden cooling very small crystals were obtained which dissolved sharply when the bulb was placed in the bath and the temperature was gradually raised. The supporting handle of the bulb was constantly tapped, giving the contents an irregular rotary motion, to assist in the rapid attainment of equilibrium. In order to make the disappearance of the crystals, as well as their formation in the following determination, as distinct as possible, the bath was illuminated by a strong electric light placed directly behind it. The crystallization temperature was determined by allowing all but one or two small fragments of the crystals to dissolve. By then allowing the temperature of the bath to fall gradually, the point at which crystallization became noticeable was determined. The difference between the two temperatures determined in this way varied from  $0.2^{\circ}$  to  $0.6^{\circ}$ . Their mean, the accuracy of which was within  $\pm 0.2^{\circ}$ , was taken as the equilibrium temperature for saturation.

#### Calculation of the Weight of Water in the Vapor Phase.

At temperatures below  $60^{\circ}$ , where the volume of the gas space is of the order of 1 cc., as in the present case, no correction for the weight of water in the vapor phase was needed. Above  $60^{\circ}$ , the correction becomes appreciable and at higher temperatures failure to take this factor into consideration may readily introduce an error of 1% or more in the calculation of the composition of the liquid phase.

The volume of each bulb being known, the fraction of the volume occupied by the liquid at the saturation temperature was "estimated" and from this estimated volume and the total weight of the solution, an approximation of its density was obtained. The density estimations at slightly different temperatures were averaged, as were also the temperatures themselves, and the results plotted. In as much as these densities, along with the density of saturated ammonium bromide solution at  $15^{\circ}$ ,<sup>2</sup>

<sup>1</sup> Cf. Hartley, *Loc. cit.*

<sup>2</sup> Eder, *Ibid.*

fall on a fairly smooth curve, the approximation was considered sufficiently close for the purpose. The densities used were:

$t$ .....	$15^{\circ}$	$113^{\circ}$	$137^{\circ}$	$158^{\circ}$
$d$ .....	1.29	1.66	1.71	1.76

The density of the saturated solution read from this curve was then employed to calculate the volume of the liquid phase in any given case and, by subtracting from the total volume of the bulb,<sup>1</sup> the volume of the gas space was obtained.

The vapor pressure of the solution was taken to be the same fraction of the vapor pressure of water, at a given temperature, as the molar fraction of water in the system. This again is only a rough approximation, but sufficiently accurate for the purpose.

Fig. 2.—The solubilities of ammonium bromide in water.

The weight of water vapor was calculated from its volume and partial pressure as thus obtained, and was subtracted from the total weight of water in the bulb before the composition of the liquid phase was calculated.

<sup>1</sup> The increase in volume of the bulb due to the expansion of the glass was estimated to be negligibly small.

The correction thus applied varied from zero at low temperatures to 0.0019 g. at one of the higher temperatures, out of a total weight of 0.1 to 0.2 g. of water.

### Experimental Results.

The results of the determinations of the solubility of ammonium bromide in water are given in Table I.

TABLE I.—SOLUBILITIES OF NH<sub>4</sub>Br IN H<sub>2</sub>O—OBSERVATIONS.

Weight NH <sub>4</sub> Br.	Weight H <sub>2</sub> O.	Vol. of bulb, cc.	Weight H <sub>2</sub> O vapor (calc.), gram.	Ratio, weight NH <sub>4</sub> Br H <sub>2</sub> O (liquid)	Molar fraction. NH <sub>4</sub> Br.	Temp. of satn.

In one instance (Experiment marked \* Table I) a point on the meta-stable portion of the lower solubility curve was obtained. This was accomplished by placing the cold tube in the bath maintained at the temperature predicted by prolongation of the lower curve and the known composition of the contents of the bulb. In this manner it was possible to completely dissolve the crystals at a temperature nearly  $1^\circ$  below that at which the same sample, when in the form stable at that temperature, was found to dissolve. In order to determine the saturation temperature for the stable form, the temperature of the bath was raised a degree or so above the transition point and the solid was allowed to stand several minutes in contact with the solution (without shaking). On lowering the temperature slightly and determining the saturation temperature in the usual manner the point on the equilibrium curve was obtained.

The solubilities from 0 to  $100^\circ$  do not agree with those given by Eder. To show the amount of the discrepancy, his values are plotted with our own results in Fig. 2. He gives no description of his method of determining the solubility.

### Summary.

Heating and cooling curves showed the transition point of ammonium bromide to lie between  $130^\circ$  and  $143^\circ$ . The solubilities in water from 0 to  $170^\circ$  were determined by the closed tube method. A well defined break in the solubility curve occurs at  $137.3^\circ$ , the transition temperature. The solubility measurements from 0 to  $100^\circ$  do not agree with the only ones heretofore available in the literature.

### [CONTRIBUTION FROM THE CHEMICAL LABORATORY OF THE UNIVERSITY OF CALIFORNIA.] THE PRACTICAL INSTALLATION OF THE DOUBLE COMBINATION POTENTIOMETER.

By MERLE RANDALL, F. RUSSELL v. BICHOWSKY AND W. H. RODEBUSH.

Received April 11, 1916.

The advantages of multiple thermoelements for use in calorimetry, and the design and installation of suitable potentiometers for these and

other precise potential measurements have been discussed at length by White.<sup>1</sup> In attempting to install a double combination potentiometer<sup>2</sup> of highest sensitivity, certain improvements and precautions not discussed by White have been worked out.

Our instrument was originally designed for use with lead storage cells as the primary source of electromotive force. The lead cell is not satisfactory. In the first place the e. m. f. is unnecessarily high, thus increasing leakage difficulties. In the second place the cell has a high temperature coefficient and even at constant temperature the e. m. f. is not particularly constant. Thus the instrument requires frequent comparison with the standard cell. On the other hand, the large size Hulett<sup>3</sup> standard battery is free from these defects, our batteries seldom varying under working conditions by more than 0.0001 volt. However, because the e. m. f. of the Hulett battery is but slightly greater than that of the standard cell, certain changes in the design of the instrument were necessary. These changes affect only the low-resistance side of the instrument. In the original instrument the battery current flowed through both the dial resistances of 99 ohms and an auxiliary resistance of 1018 ohms. This last coil was used not only as an auxiliary resistance, but also for checking the battery current against the standard cell (1.0181 volts at 25°). The Hulett cell does not give a sufficient e. m. f. to force a current of 0.001 amp. through these two resistances. We therefore substituted for the 1018 ohms coil in the battery circuit a coil (W) of 919.1 ohms, making the total resistance of the battery circuit inside the potentiometer 1018.1 ohms. We then re-arranged the connections so that the battery current is checked against the standard cell through this total resistance, and the old coil is used as a substitute resistance when the potentiometer is cut out.

The precise details of the connections as modified will be made clear by reference to Fig. 1 which combines Figs. 7, 10 and 11 of White<sup>4</sup> into a simple schematic diagram. The block letters refer to the same parts as in Fig. 11, and the roman to the letters given to the binding posts by the makers of our instrument. What the significance of this last lettering is we have been unable to ascertain. The heavy lines indicate those parts included in the potentiometer box. In practice switches  $E_1$ ,  $E_2$  and  $E_3$  are combined into a single 3-pole double-throw switch. Similarly, switch M is a 4-pole double-throw and SC and SH are 2-pole double-throw switches. Switches SC and SH correspond to the unlettered switches of White, Fig. 12.

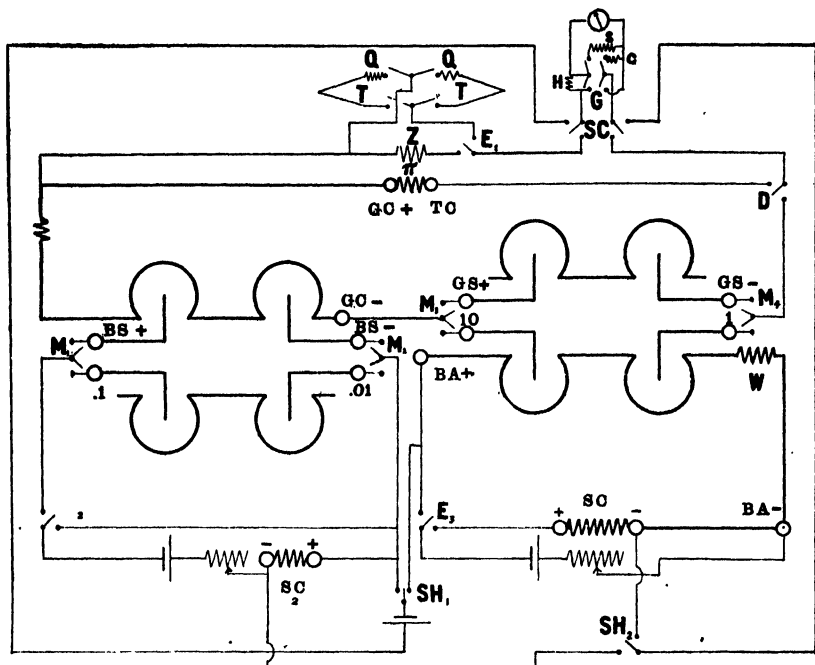

Fig. 1.

**The Elimination of Parasitic Thermoelectric Effects.**—In our installation parasitic thermoelectric effects have been reduced to less than 0.01 microvolt; in fact none are detectable within the limits of sensibility of the galvanometer. This result has been obtained by carefully eliminating all metals except copper in the external circuits, and by entirely enclosing the instrument, wiring and galvanometer.

The special switches which White recommends have been improved by specifying copper instead of brass clips for fastening the wire to the switch contacts, thus providing a continuous copper circuit. It is, of course, unnecessary, and in fact undesirable from a mechanical standpoint, that the screws, bolts, etc., be of copper.

Fig. 2.

While the "clothes-pin" contact of White is entirely satisfactory, we have found the form of binding post shown in Fig. 2 to be more rugged and convenient for a permanent installation. It consists of a threaded copper rod, A, a threaded copper bushing, B, a brass binding nut, C, and a brass nut, D, soldered to the copper rod. The permanent connection is made by soldering to the copper rod. This binding post is much cheaper than an all copper post, is thermoelectrically as satisfactory, and mechanically much better.

The remaining thermal parasitics are mainly in the brass binding posts of the galvanometer and potentiometer box. These brass binding posts should be replaced by posts of the type described in the preceding paragraph. In our instrument we have not made these replacements but have eliminated these effects by complete thermal enclosure.

**Insulation.**—For an instrument that is to be used in a chemical laboratory it is essential that there be as few exposed electrical parts as possible, and that the insulation between different exposed parts be of such a nature that it can easily be renewed. Properly treated paraffin forms a most satisfactory insulation. In our instrument all the wires are led through glass tubes which are embedded in paraffin. The paraffin used for purposes of insulation should be of the best quantity obtainable, should be boiled before using, and should be cast in thin layers, each of which is allowed to harden before a successive one is applied. Paraffin thus treated has an effective resistance of more than  $10^{11}$  ohms per cm./cm<sup>2</sup>. The complete enclosure of all of the wires in one solid block of paraffin makes local electrical shielding almost unnecessary. The whole instrument, galvanometer, and connected apparatus must, of course, be shielded by White's method. In many cases where the insulation is not perfect we have found local shielding a positive disadvantage.<sup>1</sup> The switches should be particularly well insulated. We have replaced the fiber parts by bakelite and have submerged the bases entirely in paraffin, thus allowing a renewal of the surface insulation from time to time.

For convenience our instrument is mounted as a unit upon a wooden table 36" × 36". The Hulett batteries are carried on a shelf below the table. All the wiring is brought underneath the table through glass, paraffin-filled tubes, and the connections cast as a unit in a shielded paraffin block. Following the suggestion of White, the various switches, rheostats, and resistances are mounted in a tin-lined wooden box and operated by draw rods. It is of great advantage to enclose the sliding contacts on the top of the potentiometer box and to operate the dials by means of shielded extension handles. Connections to the standard cell, batteries, galvanometer and thermoelements are made by means of copper binding posts outside the enclosing case.

We have found the unprotected galvanometer the source of very serious thermoelectric forces. At the suggestion of Prof. Lewis it was enclosed in a heavy sheet copper box with a small plane glass window. The box is connected with the shielding system. The telescope is mounted on the top of the case enclosing the switches 50 cm. from the galvanometer mirror and the strongly illuminated scale is several meters away and at such a height that troublesome double reflections are avoided. The galvanometer switches are operated by foot pedals.

<sup>1</sup> Leakage currents may best be tested for by short-circuiting the thermocouple.

**The Galvanometer.**—For use with multiple thermoelements of 20 to 50 couples a galvanometer of the following specifications<sup>1</sup> is recommended: resistance 30 ohms, external critical damping resistance 400 ohms, period 7 sec., sensitivity 4 mm. per microvolt with the damping resistance in series. The potentiometer is usually used with several thermocouples which have different resistances. Instead of changing  $Z$  (Fig. 1) to correspond to the resistance of each thermocouple, it is fixed at 400 (C. D. R. of galvanometer)—105.5 (resistance of remainder of external galvanometer circuit) and an auxiliary resistance,  $Q$ , placed in series with each thermocouple. This resistance  $Q$  is wound of copper wire so as to be free of thermoelectric forces, and has such a value that its resistance added to that of the thermocouple equals  $Z$ .

For the above galvanometer the resistance  $S$  should have the value 400 ohms, and  $H$  3572 ohms<sup>2</sup> in order that the galvanometer can be set to give  $1/10$  sensitivity.

Our instrument as finally set up has no detectable thermoelectric parasitics, and only an extremely constant leakage e. m. f. of slightly less than 0.1 microvolt.

## THE TEMPERATURE EFFECT IN DIALYSIS AND A SIMPLE RAPID DIALYZER.<sup>3</sup>

By MARKS NEIDLE.

Received April 27, 1916.

The speed of dialysis depends upon the following factors: First, the nature of the membrane; second, the area of the membrane which is in contact with liquid on both sides; third, the difference in concentration of diffusible substances in internal and external liquids close to the membrane; fourth, the temperatures of the internal and external liquids.

By utilizing, especially the third and fourth principles, it is possible to prepare large quantities of inorganic hydrosols, containing only minute amounts of electrolytes, in a comparatively short time. The method consists in suspending a parchment paper membrane of about one liter capacity in a two liter beaker containing about a liter of the solution to be dialyzed. Distilled water is run at a fairly constant rate into the membrane, which is maintained a little more than half full by means of an automatic syphon. The colloidal solution which is in the beaker is heated to any desired temperature (70–90°).

<sup>1</sup> For use with low-resistance couples the critical damping resistance can be reduced to 150 ohms with an increase of sensitivity.

<sup>2</sup> For a galvanometer 150 ohms C. D. R.,  $S = 150$  ohms, and  $H = 1625$  ohms.

<sup>3</sup> Presented at the spring meeting of the American Chemical Society, 1916.

Wobbe<sup>1</sup> and Nicolardot<sup>2</sup> speak of a process of hot dialysis but they neither describe their methods nor discuss the advantages of dialyzing in this way. In connection with a device, which is essentially a modified Soxhlet apparatus, for the quantitative and rapid dialysis of small volumes of colloidal solutions, Golodetz<sup>3</sup> mentions that the dialysis membrane which is above the boiling flask is heated to about 40° to 50°, this being favorable to rapid dialysis.

Beyond these mere statements it seems that the temperature effect in dialysis has been completely neglected. Its importance is evident from the fact that the simple apparatus represented in the diagram gives in twenty days a hydrous ferric oxide hydrosol, as pure as, if not purer, than the same hydrosol prepared by dialysis in the cold for six months. A colloidal solution satisfactory for most purposes may be obtained in eight to ten days, while the usual method requires about a month.

The temperature effect becomes apparent as soon as we regard the colloidal solution as a two-phase system in which the electrolyte is distributed between the disperse phase and the dispersion medium according to the laws of adsorption. If the dialyzing membrane is impermeable to the disperse phase, only the electrolyte which is not adsorbed can diffuse directly. Now, if the colloidal solution is heated, this portion of the electrolyte will diffuse more rapidly through the membrane and since the diffusion coefficient<sup>4</sup> increases about 2% per degree, the effect of a temperature increase of 50–70° will be very considerable.

As the electrolyte in the dispersion medium diffuses through the mem-

<sup>2</sup> *Ann. chim. phys.*, 366, 348 (1905).

<sup>3</sup> *Z. physiol. Chem.*, 86, 315–24 (1913).

<sup>4</sup> Nernst, *Theoretische Chemie*, 7th ed., p. 400.

brane, the equilibrium of distribution of the electrolyte is disturbed, and part of the adsorbed electrolyte diffuses into the dispersion medium from which it can now dialyze. Heating accelerates the re-establishment of equilibrium and consequently hastens dialysis.

Furthermore, in general, adsorption decreases<sup>1</sup> considerably with rise in temperature. For a given total concentration of electrolyte in a colloidal solution at equilibrium there will be more of it in the dispersion medium if the solution is heated, and since diffusion through the membrane depends only on the concentration of the electrolyte in the dispersion medium, heating should be favorable to rapid dialysis.

By placing the solution to be dialyzed in the outside vessel (the beaker) and heating, the large increase in volume due to osmosis, which results in the usual procedure, is avoided. An equilibrium sets in between evaporation from the colloidal solution and osmosis of water into it through the membrane, and the volume remains practically constant. Or, if desired, the solution may be concentrated during dialysis.

The steady flow of distilled water inside the dialyzer helps dialysis by maintaining a maximum difference of concentration of diffusible substances on both sides of the membrane, and also by maintaining within the latter a lower temperature than outside, which introduces the Soret<sup>2</sup> phenomenon.

Our experience is that parchment paper membranes of about one liter capacity are far easier to prepare than collodion membranes of the same size. They stand rough usage, a temperature of over 90° for a long period, and cost very little.

## ON THE EQUILIBRIA OF MERCURIC CHLORIDE WITH OTHER CHLORIDES.

By G. A. LINHART.

Received March 6, 1916.

In a recent paper<sup>3</sup> it is shown that the association of mercuric chloride in water solution depends both on the concentration and the temperature, and that the degree of association ranges, in saturated solutions, from 6% at 0° to 58% at 100°. It is, therefore, not surprising that in the absence of these data, previous investigators were not able to account for the abnormal behavior of mercuric chloride in water solution with reference to its molecular weight, distribution ratio, and solubility. Of particular interest are the attempts made by several investigators to establish the type or types of complex compounds which mercuric chloride

<sup>1</sup> *Freundlich Kapillarchemie*, 169-173.

<sup>2</sup> Nernst, *Theoretische Chemie*, 7th ed., p. 801.

<sup>3</sup> *THIS JOURNAL*, 37, 258 (1915).

forms with other chlorides in solution. The results were, of course, entirely unsatisfactory as is evident from the polemics that followed.<sup>1</sup> It is the purpose of this paper to harmonize these opposing views, which resulted partly from the use of unreliable methods of analyses, but chiefly from not taking into account the formation of the double molecules of mercuric chloride in solution.

It has been shown fairly conclusively<sup>2</sup> that in a water solution of mercuric chloride there are two types of molecules,  $\text{HgCl}_2$  and  $\text{Hg}_2\text{Cl}_4$ , which combine to form complex compounds with sodium chloride in water solution, and it only remains to establish, if possible, the type or types of these complexes.

Assuming *only* those complexes which have been isolated<sup>3</sup> from water solutions in definite crystalline forms and of definite chemical composition, then the reactions between the chloride ions of the sodium chloride and the two kinds of molecules of mercuric chloride may be represented by the equations

(a),  $(\text{HgCl}_2) + (\text{Cl})^- \rightleftharpoons (\text{HgCl}_3)^-$ ; (b),  $(\text{Hg}_2\text{Cl}_4) + (\text{Cl})^- \rightleftharpoons (\text{Hg}_2\text{Cl}_5)^-$  when the mercuric chloride is in excess, and by

(c),  $(\text{HgCl}_3)^- + (\text{Cl})^- \rightleftharpoons (\text{HgCl}_4)^{--}$ ; (d),  $(\text{Hg}_2\text{Cl}_5)^- + (\text{Cl})^- \rightleftharpoons (\text{Hg}_2\text{Cl}_6)^{--}$ ; (e),  $(\text{Hg}_2\text{Cl}_6)^{--} + (\text{Cl})^- \rightleftharpoons (\text{HgCl}_3)^- + (\text{HgCl}_4)^{--}$  when the sodium chloride is in large excess.

It is evident that in any concentration of the reacting substances the total concentration of the sodium chloride and the mercuric chloride may be expressed by the sums

$$(\text{HgCl}_2) + (2\text{Hg}_2\text{Cl}_4) + \frac{(\text{HgCl}_3)^-}{\gamma} + \frac{(\text{HgCl}_4)^{--}}{\gamma^2} + \frac{(2\text{Hg}_2\text{Cl}_5)^-}{\gamma} + \frac{(2\text{Hg}_2\text{Cl}_6)^{--}}{\gamma^2} = \Sigma \text{HgCl}_2.$$

$$\frac{(\text{HgCl}_3)^-}{\gamma} + \frac{(2\text{HgCl}_4)^{--}}{\gamma^2} + \frac{(\text{Hg}_2\text{Cl}_5)^-}{\gamma} + \frac{(2\text{Hg}_2\text{Cl}_6)^{--}}{\gamma^2} + \frac{(\text{Cl})^-}{\gamma} = \Sigma \text{NaCl}.$$

<sup>2</sup> THIS JOURNAL, **37**, 271 (1915).

<sup>3</sup> It is interesting to note that by saturating concentrated aqueous hydrochloric acid solutions with mercuric chloride and cooling to incipient crystallization Ditte obtained compounds of the following composition:

Substance.	60°.	30°.	15°.	5°.	-10°.
$\text{HgCl}_2$ .....	86.58%	82.30%	78.97%	67.10%	57.60%
$\text{HCl}$ .....	3.86	5.54	5.33	12.04	15.51
$\text{H}_2\text{O}$ .....	9.56	12.16	15.70	20.86	26.88
$\text{HHg}_3\text{Cl}_7.5\text{H}_2\text{O}$	$\text{HHg}_3\text{Cl}_8.4\text{H}_2\text{O}$	$\text{HHg}_2\text{Cl}_6.6\text{H}_2\text{O}$	$\text{H}_2\text{Hg}_2\text{Cl}_6.7\text{H}_2\text{O}$	$\text{H}_2\text{HgCl}_4.7\text{H}_2\text{O}$	
			$\text{H}_2\text{HgCl}_4.7\text{H}_2\text{O}$		

The corresponding potassium salts, with the exception of the first, were first prepared by Bonsdorf (see Abegg's *Handbuch der anorg. Chem.*, II, 2).

It is here assumed that the compounds  $\text{NaHgCl}_3$ ,  $\text{NaHg}_2\text{Cl}_4$ , and  $\text{NaCl}$  in the same (water) solution dissociate to the same extent. The degree of dissociation of the corresponding divalent ions will then be equal to<sup>1</sup> ( $\gamma^2$ ), so that the dissociation factors in the equilibrium equations cancel out and we have

$$\frac{(\text{HgCl}_3)^-}{(\text{HgCl}_2)(\text{Cl})^-} = K_1. \quad (3) \qquad \frac{(\text{Hg}_2\text{Cl}_6)^-}{(\text{Hg}_2\text{Cl}_4)(\text{Cl})^-} = K_3. \quad (5)$$

$$\frac{(\text{HgCl}_4)^{--}}{(\text{HgCl}_3)(\text{Cl})^-} = K_2. \quad (4) \qquad \frac{(\text{Hg}_2\text{Cl}_6)^{--}}{(\text{Hg}_2\text{Cl}_5)(\text{Cl})^-} = K_4. \quad (6)$$

Expressing now these equations in terms of the known quantities  $(\text{HgCl}_2)$ ,  $(\text{Hg}_2\text{Cl}_4)$ ,  $\Sigma\text{HgCl}_2$ , and  $\Sigma\text{NaCl}$  and collecting common terms into  $N$ ,  $M$ ,  $N'$  and  $M'$  we finally obtain

$$-\frac{N}{2M} \pm \sqrt{\frac{\Sigma(\text{HgCl}_2) - (\text{HgCl}_2) - (2\text{Hg}_2\text{Cl}_4)}{M}} + \left(\frac{N}{2M}\right)^2 =$$

$$-\frac{N'}{2M'} \pm \sqrt{\frac{\Sigma(\text{NaCl})}{M'}} + \left(\frac{N'}{2M'}\right)^2. \quad (7)$$

The concentrations of the  $\text{HgCl}_2$  and  $2\text{Hg}_2\text{Cl}_4$  are obtained from partition measurements as described in a previous paper.<sup>2</sup> By means of Equation 7, in which the only unknown quantities are the equilibrium constants (included in  $N$ ,  $M$ ,  $N'$  and  $M'$ ), we can test the accuracy of the extrapolated constants, which were derived as follows:

From a study of the velocity of the reaction<sup>3</sup> between mercuric chloride and sodium formate to form  $\text{HgCl}_4^{2-}$  it was found that the specific reaction rate gradually decreased with increase in concentration of  $\text{NaCl}$  formed in the reaction, but that in very dilute solution, the velocity coefficients remained practically constant during the entire course of the reaction, because the amount of complex compounds formed under these conditions is extremely small. It may, therefore, be safely assumed, as a first approximation, that in the experiment with 0.03 molal mercuric chloride and 0.01 molal of sodium chloride, the chief sodium chloride complex in the solution is  $\text{NaHgCl}_3$ , as indicated in Equation *a*. Introducing the results of this experiment in Equation 3, it was found that

$$\frac{(\text{HgCl}_3)^-}{(\text{HgCl}_2)(\text{Cl})^-} = K_1 = 9.8 \text{ at } 25^\circ. \quad (8)$$

The amount of  $\text{HgS}$  obtained from the analysis of  $3/4$  of the benzene phase or 150 cc., was 0.0745 g., corresponding to 0.002141 mol of mercuric chloride per liter of solution of benzene phase, and this was denoted by  $\text{Cb}$ . If now  $R_\infty$  denotes the true distribution ratio (11.9) of mercuric chloride between water and benzene then,  $\text{Cb}R_\infty$  = the concentration of the

<sup>1</sup> Adams and Rosenstein, *THIS JOURNAL*, 36, 1464 (1914).

<sup>2</sup> *Loc. cit.*

<sup>3</sup> *THIS JOURNAL*, 37, 73 (1915).

**pe•lite**

$$\frac{(\text{Hg}_2\text{Cl}_4)}{(\text{HgCl}_2)^2} = K = 0.3.$$

Now substituting the experimental results in Equation 8 we have

$$\frac{\Sigma(\text{HgCl}_2) - (\text{Cb}) - (\text{CbR}_\infty) - 2K(\text{Cb})^2(\text{R}_\infty)^2}{(\text{CbR}_\infty)[\Sigma(\text{NaCl}) - (\text{NaHgCl}_2)]} = 9.8. \quad (9)$$

(In the paper just cited (10)<sup>4</sup>  $K = 3$ ,  $K$  being calculated on the basis of millimols instead of mols per liter of solution as in the above.)

In order to evaluate  $K_2$ ,  $K_3$  and  $K_4$ , the following experiments were performed:<sup>1</sup>

<sup>1</sup> In order to determine the relative amounts of the several complex substances in the solution, the distribution ratios

were measured. This method was preferred because it is capable of yielding results of a very high degree of accuracy, if the method of analysis, given in a previous paper dealing with the distribution ratio of mercuric chloride between water and benzene, is strictly followed.

The reliability of this method of determining the mercuric chloride in the benzene phase is even more evident in this work than in the previous as a glance at the distribution ratios will show. Thus in Table I, Expt. 4, a 0.2% error in the water phase would correspond to a 21% error in the benzene phase, if the latter were determined by difference. It was therefore deemed desirable and sufficient to determine the amount of mercuric chloride in the benzene phase only, and to take the difference between the initial concentration and the amounts thus found as the quantity of mercuric chloride in the water phase. The experimental procedure was exactly the same in every detail as already described in a previous article (THIS JOURNAL, 37, 260 (1915)) except that the desired amount of pure sodium chloride was added to the contents of of the 250 cc. flask before it was filled to the mark with distilled water at the desired temperature.

In the above table  $\Sigma(\text{NaCl})$  denotes the total concentration of the sodium chloride in the water phase in mols per liter of solution.

$\Sigma(\text{HgCl}_2) + (\text{Cb})$  denotes the total concentration of the mercuric chloride in the water phase and benzene phase.

$\text{HgS}$  from 150 cc.  $\text{C}_6\text{H}_6$  denotes the number of grams of mercuric sulfide obtained from the analysis of  $\frac{3}{4}$  of the benzene phase, the total being 200 cc.

$(\text{Cb})$  denotes the number of mols of mercuric chloride in the benzene phase in mols per liter of solution.

$\Sigma(\text{HgCl}_2)$  denotes the total number of mols, both free and combined, of mercuric chloride in the water phase per liter of solution.

$R$  denotes the distribution ratio of the system

Since, in Experiment 4, Series I, the amount of free mercuric chloride is very small, as is evident from the amount of mercuric chloride found in the benzene phase, then, according to Equations *a*, *c* and *e*, the only complex ions we need to consider here (as a first approximation) are  $(\text{HgCl}_3)^-$  and  $(\text{HgCl}_4)^{--}$ . Substituting the results of this experiment into Equation 9 we have:

$$\frac{(\text{HgCl}_3)^-}{(\text{HgCl}_2)(\text{Cl})^-} = \frac{\Sigma(\text{HgCl}_2) - (\text{Cb}) - (\text{CbR}_\infty) - 2K(\text{Cb})^2(R_\infty)^2 - (\text{Na}_2\text{HgCl}_4)}{(\text{CbR}_\infty)[\Sigma(\text{NaCl}) - (\text{NaHgCl}_3) - (2\text{Na}_2\text{HgCl}_4)]} = 9.8$$

Whence  $\text{Na}_2\text{HgCl}_4 = 0.06$ ,  $\text{NaHgCl}_3 = 0.03$ ,  $\text{NaCl} = 0.35$  and

$$\frac{(\text{HgCl}_4)^{--}}{(\text{HgCl}_3)^-(\text{Cl})^-} = 5.7 = K_2 \text{ approximately.}$$

Similarly an approximate value for  $K_3$  was obtained by plotting on a large scale  $\text{Cb}$  (millimols for 10 cm.) against  $\Sigma\text{NaCl}$  (millimols per 1 cm.) of Series I. The extrapolated values (given in Table I in parentheses) were then substituted into Equation 9,

$$\frac{(\text{HgCl}_3)^-}{(\text{HgCl}_2)(\text{Cl})^-} = \frac{\Sigma(\text{HgCl}_2) - (\text{Cb}) - (\text{CbR}_\infty) - 2K(\text{Cb})^2(R_\infty)^2 - (2\text{NaHg}_2\text{Cl}_5)}{(\text{CbR}_\infty)[\Sigma(\text{NaCl}) - (\text{NaHgCl}_3) - (\text{NaHg}_2\text{Cl}_5)]} = 9.8,$$

where, according to Equations *a* and *b* we may, as a first approximation, neglect the quantities  $\text{Na}_2\text{Hg}_2\text{Cl}_6$  and  $\text{Na}_2\text{HgCl}_4$ . We then obtain  $\text{NaHg}_2\text{Cl}_5 = 0.000188$ ,  $\text{NaHgCl}_3 = 0.002198$ ,  $\text{HgCl}_2 = 0.0858$ ,  $\text{NaCl} = 0.002614$  and  $\text{Hg}_3\text{Cl}_4 = 0.002209$ , and finally

$$\frac{(\text{Hg}_3\text{Cl}_4)^-}{(\text{Hg}_3\text{Cl}_4)(\text{Cl})^-} = 33 = K_3 \text{ approximately.}$$

Finally  $K_4$  was obtained by substituting the approximate values for the equilibrium constants and the experimental results of every experiment

into the general Equation 7. The four equilibrium constants thus obtained were then readjusted in order to satisfy the summation Equations 1 and 2.<sup>1</sup> The final results are given in Table II, the headings being self-explanatory.

Av.  $K_1 = 9.8$  Av.  $K_2 = 4.9$  Av.  $K_3 = 37$  Av.  $K_4 = 19$

<sup>1</sup> It does not seem justifiable to substitute the average values of the equilibrium constants thus obtained for  $K_1 = 9.8$ ,  $K_2 = 4.9$ ,  $K_3 = 37$ ,  $K_4 = 19$  in the general Equation 7 in order to obtain "calculated values" for Cb and compare them with the "Cb found," because the deviations of the equilibrium constants from the corresponding average, although small, may well be due to the assumptions made in reference to their degree of association, which is only approximately correct.

## Conclusion.

(1) The complex compounds of mercuric chloride and sodium chloride which have been assumed to exist in water solution and whose presence have been confirmed sufficiently by experimental evidence, have all been prepared in solid crystalline form.

(2) No complex mercuric chloride of sodium, potassium or hydrogen has been shown to exist either in the solution or in solid form having a higher chloride content than is indicated by the type  $\text{Na}_2\text{HgCl}_4$ . It is especially interesting to note that from a saturated solution of mercuric chloride and hydrochloric acid at about  $-10^\circ$  no compound richer in HCl than  $\text{H}_2\text{HgCl}_4$  could be obtained by Ditte, although the solution was supersaturated with HCl gas. This is a conclusive test since the increase of the hydrochloric acid content in these compounds with the fall in temperature should be favorable, due to the fact that the solubility of hydrochloric acid increases with a decrease in temperature while the solubility of mercuric chloride decreases.

(3) The complex  $\text{H}_3\text{HgCl}_5$  given in Abegg's *Anorganische Chemie*<sup>1</sup> by Ley is the result of a misunderstanding of the original data from which it was calculated, as is shown below.

16°.		
Mols HCl. a.	Mols $\text{HgCl}_2$ . c.	a/c.
1.57	1.52	1.0
2.09	2.83	1.0
4.03	4.34	1.0
6.44	5.11	1.3
9.51	5.06	1.7
16.00	6.37	2.0
22.00	6.90	3.3

From these figures Ley concluded that a compound containing the anion  $(\text{HgCl}_2)_x(\text{Cl})_{2x}$  must exist in solution. As a matter of fact on consulting the original data, it was found that Ditte claims to have added the

## A STUDY OF THE SILVER ARSENATE TEST FOR ARSENIC.

By L. J. CURTMAN AND P. DASCHAVSKY.

Received February 18, 1916.

The precipitation of arsenic in the form of an arsenate, by silver nitrate in a neutral solution is so striking that it recommends itself as an excellent confirmatory test. However, the results obtained by students in this laboratory have been so irregular that it was thought worth while to investigate this test for the purpose of ascertaining the conditions under which it could be relied upon to give constant results. It was also the object of the experiments recorded in this paper to determine whether this test is sufficiently sensitive to serve as a confirmatory test for amounts of arsenic from 1-5 mg.

**Preparation of Standard Sodium Arsenate Solution.**—41.6 g.  $\text{Na}_2\text{HAsO}_4 \cdot 7\text{H}_2\text{O}$  were dissolved in water and the volume made up to a liter. 20 cc. portions of this solution were run out from a buret and the arsenic determined gravimetrically by the method given by Treadwell.<sup>1</sup> The results of well-agreeing determinations gave the solution a value of 10 mg. of As per cc. By suitable dilution in volumetric flasks, solutions of lower concentrations were obtained.

**Determination of the Sensitiveness of the Test.**—By means of graduated pipets, definite amounts of the standard arsenate solution were introduced into a series of test tubes. 2 cc. of a silver nitrate solution of strength 50 mg. Ag per cc. were then added. After the addition of one drop of a 1% solution of phenolphthalein, the solutions were made alkaline with dilute  $\text{NH}_4\text{OH}$  and finally made just acid with 5% acetic acid. After standing for several minutes the tubes were examined and the results compared with a blank run under the same conditions. The following results were obtained:

TABLE I.

No.	As (mg.).	Result.	No.	As (mg.).	Result.
1	10.00	Heavy precipitate	5	0.10	Faint precipitate
2	5.00	Heavy precipitate	6-7	0.05	Faint precipitate on standing
3	1.00	Small precipitate	8-10	0.02	Brown coloration. Limit
4	0.50	Small precipitate	11-12	0.01	Negative

The above results show that the limit of the test (0.02 mg. in a volume of 3 cc.) represents a concentration of 1 part in 150,000. While this limit-

<sup>1</sup> Treadwell "Quantitative Analysis," translated by H. T. Hall (1904), p. 163.

ing amount of arsenic can be readily recognized when compared with a blank, decided and unmistakable results are obtained with 0.05 mg. which for routine qualitative work is the practical limit of the test. By the use of an indicator and a 5% solution of acetic acid, added drop by drop, a practically neutral solution is readily obtained.

**Influence of Ammonium Salts.**—In the above experiments care was taken to avoid the addition of an excess of  $\text{NH}_4\text{OH}$ . In systematic analysis the arsenate is formed by the solution of the sulfide in an excess of nitric acid and the test applied after the free acid has been neutralized by ammonia. This procedure results in the formation of ammonium salts which, it was thought, might diminish the sensitiveness of the test and thus account for the failure of students to detect from 1 to 5 mg. of arsenic. To ascertain whether or not ammonium nitrate exercises any influence on the test, the following experiments were made. The procedure was the same as that already described. The results are given in Table II.

TABLE II.

No.	As (mg.).	$\text{NH}_4\text{NO}_3$ , g.	Total Vol., cc.	Test.
1-6.....	1.0	0.0-5.0	8.0	Good
7-12.....	0.2	0.0-5.0	9.0	Good

The above results show that 5 g. of  $\text{NH}_4\text{NO}_3$  do not interfere with the detection of small amounts of arsenic by this test.

**Sensitiveness of the Test in Systematic Analysis.**—To determine whether small amounts of arsenic could be detected by this test in systematic analysis, the following test analyses were made. The procedure was as follows: The solution, the volume of which was about 20 cc., was neutralized with  $\text{NH}_4\text{OH}$ , 2.5 cc. conc.  $\text{HCl}$  added, heated to boiling and treated with  $\text{H}_2\text{S}$ . The volume was then made up to 100 cc. and again treated with  $\text{H}_2\text{S}$  till precipitation was complete. The precipitate was collected on a filter, transferred to a beaker, heated for 5 minutes with 10 cc. conc.  $\text{HCl}$ , diluted and filtered. The residue, after washing free from chlorides with hot water, was transferred together with the filter to an evaporating dish, boiled with 2 cc. conc.  $\text{HNO}_3$  till no more fumes of the oxides of nitrogen were given off, diluted and the mixture filtered on a small filter. The latter was then washed five times with water,

TEST ANALYSES.

No.	As (mg.).	Sb (mg.).	Sn (mg.).	Result.
1.....	5	...	...	Reddish ppt.
2.....	5	5	5	Reddish ppt.
3.....	5	500	...	Small reddish ppt.
4.....	5	...	500	Small reddish ppt.
5.....	5	250	250	Small reddish ppt.
6.....	1	250	...	Small reddish ppt.
7.....	0.5	250	...	Reddish cloudiness
8.....	0.0	250	...	Pale yellow coloration

the combined filtrate and washings concentrated to 2 cc. and transferred to a test tube. The test was then carried out in the manner already described in the determination of the sensitiveness of the test. The preceding results were obtained.

The preceding results show that the silver arsenate test is capable of detecting as little as 0.5 mg. of arsenic in systematic analysis.

### Summary.

1. With pure solutions of arsenate the test with silver nitrate is sensitive to 0.02 mg. of arsenic.

2. Ammonium nitrate, which is generally formed in carrying out this test, exercises no influence on the detection of 0.2 mg. of arsenic as sodium arsenate.

3. A procedure is given by which, in systematic analysis, the test is capable of detecting 0.5 mg. of arsenic with certainty.

NEW YORK, N. Y.

## THE DETERMINATION OF ALUMINIUM AS OXIDE.

BY WILLIAM BLUM.<sup>1</sup>

Received May 10, 1916.

CONTENTS.—I. Introduction. II. General principles. III. Historical. IV. Precipitation of aluminium hydroxide. 1. Hydrogen electrode studies. (a) The method; (b) Results of experiments; (c) Conclusions from hydrogen electrode experiments. 2. Selection of an indicator for defining conditions of precipitation. 3. Factors affecting the form of the precipitate. 4. Precipitation in the presence of iron. V. Washing the precipitate. VI. Separation from other elements. VII. Ignition and weighing of the precipitate. 1. Hygroscopicity of aluminium oxide. 2. Temperature and time of ignition. 3. Effect of ammonium chloride upon the ignition. VIII. Procedure recommended. IX. Confirmatory experiments. X. Conclusions.

### I. Introduction.

Although a considerable number of precipitants have been proposed for the determination of aluminium, direct precipitation of aluminium hydroxide by means of ammonium hydroxide, followed by ignition to oxide, is most commonly used, especially if no separation from iron is desired, in which case special methods must be employed. While the general principles involved in this determination are extremely simple, it has long been recognized that certain precautions in the precipitation, washing, and ignition, are necessary if accurate results are to be obtained. While, however, most of these details have been studied and discussed by numerous authors, it is noteworthy that few publications or text books have taken account of all the factors. In the present paper it seems

<sup>1</sup> Published by permission of the Director of the Bureau of Standards. This paper will appear in somewhat more detailed form as Scientific Paper No. 286, copies of which can be obtained upon request addressed to the Bureau of Standards, Washington, D. C.

desirable, therefore, to assemble the various recommendations, and to consider their basis and their accuracy. No attempt has been made, however, to include a complete bibliography. The experiments described in this paper were conducted in 1912, in connection with a study of the determination of alumina in phosphate rock. As the latter research was interrupted, this paper is confined to the direct determination of aluminium as oxide.

## II. General Principles.

In precipitations of metallic hydroxides by means of ammonia or other bases, the process may be considered as a progressive hydrolysis, brought about by the neutralization of the acid continuously set free. In the case of such hydroxides as ferric hydroxide, which are practically insoluble in bases, it may be readily shown that the solubility is decreased and precipitation rendered more complete by the addition of an excess of the precipitant, thereby increasing the hydroxyl ion concentration. In the case of amphoteric hydroxides, however, such as aluminium hydroxide, it is obvious that an excess of the base is to be avoided, and it therefore becomes desirable to select that degree of alkalinity which will ensure most nearly complete precipitation, and at the same time avoid resolution of the precipitate. As will be shown later, the study of the progress of the precipitation, and the selection of the proper "end point" of precipitation can readily be accomplished by means of the hydrogen electrode, the conditions selected being subsequently defined by means of suitable indicators.

## III. Historical.

Early recognition of the fact that, when considerable excess of ammonia is used in the precipitation of aluminium hydroxide, appreciable amounts of aluminium pass into the filtrate, led to the time honored procedure of boiling out most of the free ammonia. The latter method, however, has its defects, owing to the attack of glass vessels by the hot ammoniacal solution (leading to contamination of the precipitate with lime, silica, etc.); and to the possible resolution of alumina, when through excessive boiling the solution becomes slightly acid. Various authors have therefore urged the use of a very slight excess of ammonia with only a short period of boiling,<sup>1</sup> especially when a considerable amount of ammonium chloride is present in the solution.<sup>2</sup> While the beneficial effect of ammonium chloride in reducing the solubility of aluminium hydroxide in ammonia, has been pointed out by numerous authors, and has formed a basis

<sup>1</sup> S. L. Penfield and D. N. Harper, *Am. J. Sci.*, **32**, 107 (1886); *Chem. News*, **54**, 90, 102 (1886); W. H. Dautt, *J. Ind.-Eng. Chem.*, **7**, 847 (1915).

for the procedures recommended in most text books, few attempts have been made to explain this effect, which in some cases has been attributed to the coagulation of the colloidal aluminium hydroxide by the salt.<sup>1</sup> While undoubtedly this is an important function of the ammonium chloride, it will be shown later that the reduction of the alkalinity (hydroxyl ion concentration) of ammonia by the presence of ammonium chloride also exerts a marked influence upon the completeness of precipitation.

While many authors recommend the customary method of using an indicator such as litmus paper to detect roughly the presence of an excess of ammonia, few have suggested the accurate definition of the desired alkalinity by means of suitable indicators. Hinrichsen<sup>2</sup> used rosolic acid in a study of the effect of fluorine upon the precipitation of aluminium by ammonia, but gives no experimental or theoretical basis for its selection. Numerous authors, in efforts to develop methods for the volumetric determination of aluminium or for testing the neutrality of aluminium salts, have used various indicators for determining the beginning and completion of the precipitation of aluminium hydroxide; but few, if any, have shown that complete precipitation actually occurs at the color change selected.

#### IV. Precipitation of Aluminium Hydroxide.

##### *i. Hydrogen Electrode Studies.*

(a) **The Method.**—The application of the hydrogen electrode to a study of the changes taking place in solution during precipitations was suggested in a paper on the determination of magnesia in limestone,<sup>3</sup> and was elaborated in an article by J. H. Hildebrand,<sup>4</sup> in which are given numerous curves for such precipitations, including the action of sodium hydroxide upon aluminium sulfate. The principle of the method is very simple, involving the measurement of the electromotive force of a cell consisting of a hydrogen electrode and a calomel half cell, immersed in the solution to be investigated. The hydrogen ion concentration of the solution may then be calculated from the formula

$$\log \frac{1}{[H^+]} = \frac{\pi - 0.338}{0.058}$$

where  $\pi$  is the observed e. m. f. in volts (at 25°). The apparatus and method of measurement were essentially those used by Hildebrand and Harned, precautions being taken to exclude carbon dioxide during the titrations.

(b) **Results of Experiments.**—The data obtained by measurement of the changes in hydrogen ion concentration occurring upon addition of alkaline hydroxides to solutions of aluminium chloride are shown graphically in Fig. 1. The abscissas represent cubic centimeters of

Fig. 1.—Precipitation of aluminium hydroxide.

alkaline hydroxide added, and the ordinates on the left side are the observed e. m. fs. expressed in millivolts. On the right side the value of the ordinates is expressed in terms of hydrogen ion concentration, calculated as previously stated. Curves A, B, and C, are the same as were

published in a preceding article by the author<sup>1</sup> on the constitution of aluminates. The curve A for the neutralization of hydrochloric acid with sodium hydroxide is shown simply to indicate the normal course of such a reaction in the absence of any metals precipitable as hydroxides. While Curves B and C are chiefly of interest in relation to the formation of aluminates, they are included here in order to show the similarity in the course of the precipitations with fixed alkalis and with ammonia.

The Curve DE shows the progress of the reaction when ammonium hydroxide is added to a solution of aluminium chloride containing a small amount of free acid. In order to eliminate the influence of ammonium chloride (to which reference will be made later) the Curve DF was plotted, in which the portion F was obtained by the addition of ammonium hydroxide to a solution, in which the aluminium hydroxide had been exactly precipitated by the addition of a calculated amount of potassium hydroxide. While the Curve F should strictly, therefore, be attached to Curve C, it has been placed in its present position in order to emphasize the comparison between the effect of ammonium hydroxide with and without the presence of ammonium chloride.

(c) **Conclusions from Hydrogen Electrode Experiments.**—From the curves shown in Fig. 1, it is evident that the changes taking place during the precipitation of aluminium chloride are practically independent of the alkali used. In general, it may be seen that precipitation<sup>2</sup> begins when  $[H^+]$  is about  $10^{-3}$  and is complete before  $[H^+]$  is  $10^{-7}$ . In the case of the fixed alkalis it was pointed out in a former paper that appreciable resolution of the precipitate, probably with the formation of aluminates, occurs soon after the neutral point is passed, *e. g.*, when  $[H^+]$  is less than  $10^{-9}$ . When ammonium hydroxide is used as the precipitant, it may be seen from the Curve DE, that it is difficult to obtain a solution in which  $[H^+]$  is less than  $10^{-9}$ , even when appreciable excess of ammonia is present. While, therefore, as is to be expected, it is not possible by this method to obtain complete solution in ammonia of any considerable quantity of aluminium hydroxide,<sup>3</sup> an appreciable amount was always

<sup>1</sup> W. Blum, *THIS JOURNAL*, 35, 1499 (1913).

<sup>2</sup> By "precipitation" in this sense is meant the chemical formation of  $Al(OH)_3$ , which (especially in the absence of salts) may not actually coagulate or form a visible precipitate, until from one-third to half of the alkali required for complete precipitation has been added. The point at which a visible precipitate occurred in the different experiments was found to be very variable. The formation of such regular curves as are shown, however, indicates the improbability of the existence in solution of any definite basic salts such as have been supposed to be formed by solution of freshly precipitated aluminium hydroxide in neutral aluminium chloride or sulfate solutions. Consult H. W. Fischer, *Habilitationsschrift*, Breslau, 1908, C. B., 1909, I, 260; R. Kremann and K. Hüttinger, *Jahrb. K. K. Geol., Reichsan.*, 58, 637 (1909); C. B., 1909, II, 1200.

<sup>3</sup> *Existence of Ammonium Aluminate.* In a previous communication the evidence

found dissolved in any solutions in which  $[H^+]$  is less than  $10^{-9}$ . The effect of even small amounts of ammonium chloride in reducing the alkalinity of ammonium hydroxide is clearly shown by comparison of Curves E and F, there being present no ammonium chloride in F, and in E only the amount  $[H^+]$

equivalent to about 37 cc. of 0.2 N  $NH_4OH$ , i. e., the solution at the end was about 0.08 N in  $NH_4Cl$ . This effect of ammonium chloride is also illustrated in Fig. 2, in which the hydrogen ion concentration of various ammonia-ammonium chloride solu-

Fig. 2.—Effect of ammonium chloride upon the alkalinity of ammonia.

tions has been calculated from the ionization constant of ammonia at  $25^\circ$ .<sup>1</sup>

$$\frac{[NH_4^+][OH^-]}{[NH_4OH]} = 1.8 \times 10^{-5}$$

and that of water  $K_{w25^\circ} = 1.1 \times 10^{-14}$ , upon the assumption that the mass law holds for such solutions. For the sake of simplicity the ionization of ammonium chloride, which in solutions from N to 0.1 N varies from 75 to 85%,<sup>2</sup> has been taken as 80%. For convenience the results have been expressed in cc. of N ammonium hydroxide present in a volume of 100 cc. of ammonium chloride solutions of various concentration.

in favor of the formation in solution of definite aluminates of sodium and potassium was presented. While no such definite evidence of the existence of ammonium aluminate is available, owing to the above mentioned impossibility of securing ammonia solutions of high alkalinity, there seems to be no reason to doubt the analogy of the solutions in ammonia and the fixed alkalis. In this connection, it is interesting to consider the evidence presented by C. Renz (*Ber.*, 36, III, 2751 (1903)). This author dismisses the possibility of the existence of an ammonium aluminate, even though by an indirect method (*viz.*, solution of  $Al(OH)_3$  in  $Ba(OH)_2$  and subsequent addition of  $(NH_4)_2SO_4$ ) he was able to obtain a clear solution free from  $Ba^{++}$  and  $SO_4^{--}$ , 50 cc. of which contained 0.1 g.  $Al_2O_3$ . The fact, observed by Renz, that freshly precipitated  $Al(OH)_3$  is readily soluble in organic amines, far from being an argument against the existence in solution of ammonium aluminate, would appear to indicate that by the solution of aluminium hydroxide in any base, aluminates are formed, the maximum concentration being dependent upon the alkalinity of the resultant solution and its consequent ability to repress the hydrolysis of the aluminate.

<sup>1</sup> A. A. Noyes and R. B. Sosman, "Electrical Conductivity of Aqueous Solutions," *Carnegie Inst. Pub.*, 63, 228 (1908).

<sup>2</sup> F. W. G. Kohlrausch and L. Holborn, "Leitvermögen der Elektrolyte," p. 159 (1898).

From Fig. 2, it is evident (1) that even small additions of ammonium chloride cause a marked decrease in the alkalinity of ammonium hydroxide solutions, (2) that above 0.5 *N* an increase in the concentration of ammonium chloride has little effect, and (3) that with any reasonable concentration of ammonium chloride, it is impracticable to so limit the alkalinity that a solution in which  $[H^+]$  is less than  $10^{-9}$  (*i. e.*, one which dissolves appreciable  $Al(OH)_3$ ) is not formed when any large excess of concentrated ammonia is added. (It should be noted that 50 cc. *N*  $NH_4OH$  is about equal to 3.3 cc. conc.  $NH_4OH$ , sp. gr. 0.90.)

## 2. Selection of an Indicator for Defining the Conditions of Precipitation.

In Table I are shown the results of experiments conducted to determine which of the common indicators is most satisfactory for defining the completion of the precipitation. In each case the solution of the aluminium chloride and indicator was heated just to boiling in a platinum dish, and dilute ammonium hydroxide (about 2 *N*) was added till the first definite color change occurred. The solution was boiled for about two minutes, filtered and evaporated to dryness, and the total residue weighed after expulsion of the ammonium salts. Corrections were made for the small amounts of impurities in the distilled water and the ammonium chloride.

TABLE I.

Precipitation of  $Al(OH)_3$  by  $NH_4OH$ , Using Various Indicators.

(The  $AlCl_3$  solution, equivalent to 0.10 g.  $Al_2O_3$  was precipitated in a volume of 200 cc.)

Expt.	Indicator.	Color change $[H^+] =$ approx. <sup>1</sup>	$NH_4Cl$ added, g.	$Al_2O_3$ in filtrate.	Remarks.
1.....	<i>p</i> -Nitrophenol	$10^{-6}$	5	0.0010	
2.....	<i>p</i> -Nitrophenol	$10^{-6}$	5	0.0012	
3.....	Methyl red	$10^{-6.5}$	0	appreciable	Coagulated poorly
4.....	Methyl red	$10^{-6.5}$	5	0.0001	
5.....	Methyl red	$10^{-6.5}$	5	0.0000	
6.....	Rosolic acid	$10^{-7.6}$	0	0.0000	
7.....	Rosolic acid	$10^{-7.6}$	5	0.0000	
8.....	Rosolic acid	$10^{-7.6}$	5	0.0002	Macerated paper used
9.....	Phenolphthalein	$10^{-9}$	0	0.0004	
10.....	Phenolphthalein	$10^{-9}$	5	0.0004	

From Table I it is evident that considerable aluminium hydroxide remains unprecipitated when the solution is just alkaline to *p*-nitrophenol, while a smaller amount, but still appreciable, is redissolved when the solution is just alkaline to phenolphthalein. So far as accuracy is concerned, there is no choice between the use of methyl red and of rosolic acid. Practically, however, methyl red has been found preferable, because of its sharper color change, and because the end point is reached while approaching neutrality, *i. e.*, a slight excess of ammonia is less

<sup>1</sup> The approximate points of color change selected were measured with the hydrogen electrode at room temperature.

likely to cause resolution. Moreover, solutions just alkaline to methyl red are less likely to attack Jena or similar glassware, than are solutions slightly alkaline to rosolic acid. In using methyl red, however, it is essential to have appreciable ammonium chloride present to facilitate coagulation. The fact that coagulation occurs more readily, even in the presence of only small amounts of ammonium chloride, when the solution is just alkaline to rosolic acid, *i. e.*, when  $[H^+]$  is less than  $10^{-7}$ , would appear to indicate that the  $OH^-$  ion itself exerts a coagulating effect upon the colloid.

### 3. Factors Affecting the Form of the Precipitate.

It is difficult to obtain a precipitated colloid, such as aluminium hydroxide, in a form that is readily filtered and washed. In general, it has been recognized that while short boiling is desirable to effect coagulation, longer boiling renders the precipitate slimy and difficult to filter. As previously noted, the use of ammonium chloride is advantageous in producing the well-known salt effect in the coagulation of such a precipitate, as well as in reducing the actual solubility. These two factors were the only ones found to have a favorable influence upon the method of precipitation. The conclusion of W. E. Taylor,<sup>1</sup> that if the solution be heated to just  $66^\circ$  before the addition of ammonia, and subsequently boiled, the precipitate is "granular," could not be confirmed by R. Sudgen<sup>2</sup> nor by the author. The recommendation of A. Guyard<sup>3</sup> to add glycerol to the solution before precipitating with ammonia, was tried, and no improvement in the character of the precipitate was noted, while about 5 mg. of  $Al_2O_3$  was found in the filtrate. Similarly, the procedure of R. E. Divine,<sup>4</sup> *viz.*, precipitation in the presence of tannic acid, while it produced an appreciable improvement in the character of the precipitate, yielded a filtrate containing from 1 to 5 mg. of  $Al_2O_3$ , depending upon whether the solution was boiled for some time, or was filtered after a couple minutes' boiling.

While, therefore, it seems impossible to specify satisfactory conditions for the rapid filtration of considerable amounts of aluminium hydroxide, it is believed that for amounts of alumina up to 0.10 g.  $Al_2O_3$ , the following conditions will yield fairly satisfactory results; *viz.*: (1) the presence of at least 5 g. of ammonium chloride in a volume of 200 cc., (2) addition of dilute ammonia to the nearly boiling solution until it is just alkaline to methyl red (or rosolic acid), (3) boiling for not more than 2 minutes, and (4) filtration without waiting long for the precipitate to subside. (In some cases the precipitate was found to settle quite readily; while

<sup>1</sup> *Chem. News*, 103, 169 (1911).

<sup>2</sup> *Ibid.*, 104, 35 (1911).

<sup>3</sup> *Z. anal. Chem.*, 22, 426 (1883).

<sup>4</sup> *J. Soc. Chem. Ind.*, 24, 11 (1905).

in others it showed a tendency to rise to the surface, and would not settle, even on long standing.) The addition of macerated filter paper before precipitation has been found advantageous in aiding filtration (and also ignition), especially of large amounts of the precipitate.

#### 4. *Precipitation in the Presence of Iron.*

As previously noted, it is often necessary to precipitate ferric and aluminium hydroxides together. This can readily be accomplished by the procedure above recommended, since it was found that ferric hydroxide is completely precipitated by ammonia before the solution is alkaline to methyl red or to rosolic acid. In case sufficient iron is present to obscure the color of the indicator, it may be precipitated first by the careful addition of ammonia, and caused to settle by short boiling, after which the color of the indicator can readily be recognized in the supernatant liquid and more ammonia added if necessary, or any decided excess of ammonia may be neutralized with dilute acid, and the solution again boiled.

#### V. *Washing the Precipitate.*

Upon washing precipitates equivalent to 0.10 g.  $\text{Al}_2\text{O}_3$ , with only 75 cc. of hot water, from 0.5 to 2 mg. of  $\text{Al}_2\text{O}_3$  was found in the washings. The obvious remedy, *viz.*, washing with a solution of a volatile ammonium salt such as ammonium chloride or nitrate, has been suggested by numerous authors.<sup>1</sup> From the standpoint of the "salt" action there appears to be no preference between ammonium nitrate and chloride. The former has been used most frequently partly because of its slight advantage in assisting combustion of the filter paper, and partly because of the opinion, still prevalent, though frequently disproven, that the presence of ammonium chloride during ignition would cause loss of alumina by volatilization of the chloride.<sup>2</sup> As pointed out by W. F. Hillebrand,<sup>3</sup> when the original solution contains chlorides and it is desired to evaporate the filtrate and washings in platinum, and expel ammonium salts, it is impractical to use ammonium nitrate in the wash water, owing to attack of the platinum vessels. In the present research, therefore, a hot 2% solution of ammonium chloride was used. It was found that there was no appreciable difference in the amount of alumina dissolved by the neutral ammonium chloride solution, and that rendered slightly alkaline with ammonia, the residues obtained from 100 cc. of the washings in each case being less than 0.3 mg. The use of solutions of the pure salts, with no addition of ammo-

<sup>1</sup> W. H. Daudt, *J. Ind. Eng. Chem.*, 7, 847 (1915); Penfield and Harper, *Am. J. Sci.*, 32, 107 (1886); W. Trautmann, *Z. angew. Chem.*, 26 (Aufsatz), 702 (1913).

<sup>2</sup> It has been shown by Daudt (*Loc. cit.*) that 1% ammonium chloride solution may be used for washing precipitates containing ferric hydroxide with no loss of iron by volatilization.

<sup>3</sup> U. S. Geol. Survey, *Bull.* 422, 99 (1910).

nia, is therefore recommended, especially as solutions rendered alkaline are more likely to act upon the glass of the wash bottle and become contaminated.

### VI. Separation from Other Elements.

Owing to the relatively gelatinous condition of the precipitated aluminium hydroxide, the only practical method of eliminating elements such as the alkalis, which are likely to be present in considerable amount in the solution, is to dissolve and reprecipitate. That such a procedure is quite efficient, may be judged by the fact that from a solution containing 0.1000 g.  $\text{Al}_2\text{O}_3$ , and 10 g. of sodium chloride in a volume of 200 cc., the precipitate obtained after a single precipitation, and washing ten times with 2% ammonium chloride, weighed 0.1071 g., and contained much NaCl, while a similar precipitate which was washed only five times, dissolved in hydrochloric acid, reprecipitated and again washed five times, weighed 0.1008 g., and contained only a trace of NaCl.

It is well recognized<sup>1</sup> that the separation of aluminium from such elements as zinc, manganese, nickel, and cobalt by means of ammonia is unsatisfactory, since the alkalinity required for the resolution of their hydroxides is such as to cause appreciable solution of the aluminium hydroxide also. Moreover, it was found that even in solutions just alkaline to methyl red, oxidation and precipitation of manganese occurred so rapidly as to preclude a quantitative separation. For such separations, therefore, other procedures, *e. g.*, the basic acetate method, must be employed.

The precipitation conditions above recommended have been found especially favorable in the separation from those elements such as barium, calcium, and strontium, and to a less extent, magnesium, whose carbonates are likely to be formed by absorption of carbon dioxide, and carried down by the precipitated alumina. It has been found experimentally that in solutions containing barium and calcium, which are neutral, or even slightly alkaline to rosolic acid (*i. e.*,  $[\text{H}^+] = 10^{-7}$  to  $10^{-7.5}$ ) it is impossible to form a precipitate of the carbonates by exposure to the atmosphere.<sup>2</sup> Aluminium hydroxide precipitates obtained from solutions

<sup>1</sup> A. A. Noyes, W. C. Bray and E. B. Spear, *J. Am. Chem. Soc.*, 30, 482 and 532 (1908).

<sup>2</sup> This observation is approximately in accordance with the result obtained by calculating the alkalinity of barium chloride or calcium chloride solutions (*e. g.*, 0.1 N), saturated with respect to the neutral carbonates, in equilibrium with the normal atmosphere (see J. Johnston, *THIS JOURNAL*, 37, 2001-20 (1915)). Thus, the ionization of 0.1 N barium chloride solution may be assumed as 70%, *i. e.*,  $[\text{Ba}^{++}]$  is 0.07. Since at 16° the solubility product  $[\text{Ba}^{++}] [\text{CO}_3^{--}]$  is  $7 \times 10^{-9}$ ,  $[\text{CO}_3^{--}]$  is equal to  $10^{-7}$ . In any solutions at 16° in equilibrium with an atmosphere containing  $\text{CO}_2$  with a partial pressure P, 
$$\frac{[\text{OH}^-]^2}{[\text{CO}_3^{--}]} = \frac{3.4 \times 10^{-11}}{P}.$$
 While the ordinary atmosphere

containing 0.1000 g.  $\text{Al}_2\text{O}_3$  and calcium and barium chlorides equivalent to 0.2 g.  $\text{CaO}$  and  $\text{BaO}$  respectively (*i. e.*, twice the amount of  $\text{Al}_2\text{O}_3$ ), and washed five times with 2% ammonium chloride solution, weighed 0.0998 and 0.0999 g., and were found to be free from calcium and barium.

The beneficial effect of ammonium chloride in the separation of aluminium from magnesium has long been recognized. Formerly it was explained by the formation of a double salt, though more recently it has been attributed to the repression by the ammonium chloride, of the alkalinity of the ammonium hydroxide, to a point insufficient to precipitate the magnesium hydroxide.<sup>1</sup> The latter view is confirmed by the results of Hildebrand and Harned,<sup>2</sup> who found that  $\text{Mg}(\text{OH})_2$  is not precipitated until  $[\text{H}^+]$  is less than  $10^{-9}$ ; and by the curves shown in Fig. 2 of this paper, in which the above effect of ammonium chloride is clearly shown. That the procedure recommended is effective in the separation of aluminium and magnesium, is shown by experiments in which aluminium hydroxide (equivalent to 0.10 g.  $\text{Al}_2\text{O}_3$ ) precipitated in the presence of magnesium chloride equivalent to 0.2 g.  $\text{MgO}$ , contained less than 0.0010 g.  $\text{MgO}$ .

## VII. Ignition and Weighing of the Precipitate.

### 1. Hygroscopicity of Aluminium Oxide.

The fact that ignited  $\text{Al}_2\text{O}_3$  readily absorbs water has been recognized and pointed out by many authors.<sup>3</sup> This property has in fact been made the basis for the recommendation of the use of  $\text{Al}_2\text{O}_3$  as a dehydrating agent.<sup>4</sup> It should be noted, however, that for the latter use the  $\text{Al}_2\text{O}_3$  should not be strongly ignited. Many of the experiments that have been conducted to determine the hygroscopicity of such substances as  $\text{Al}_2\text{O}_3$  have little bearing upon analytical procedures, since no distinction was made between the amount of water absorbed, and the rate of absorption, especially during the first few minutes' exposure. Tests at this Bureau

contains about 3 parts of  $\text{CO}_2$  in 10,000 the air in a laboratory may often contain 5 parts, or more, in 10,000. In such a case  $P = 5 \times 10^{-4}$ , and therefore  $[\text{OH}^-]$  is  $0.84 \times 10^{-7}$ . If  $K_{w10} = 0.5 \times 10^{-14}$ , then  $[\text{H}^+]$  is about  $0.6 \times 10^{-7}$ , or  $10^{-7.2}$ , *i. e.*, the solution must be slightly alkaline before any  $\text{BaCO}_3$  can be precipitated by exposure to air containing the normal amount of  $\text{CO}_2$ .

From similar calculations for 0.1 *N*  $\text{CaCl}_2$ , assuming that  $[\text{Ca}^{++}][\text{CO}_3^{--}] = 0.98 \times 10^{-8}$ , it may be shown that  $[\text{OH}^-] = 1.0 \times 10^{-7}$ ; or  $[\text{H}^+] = 0.5 \times 10^{-7}$  or  $10^{-7.3}$  before any  $\text{CaCO}_3$  will be precipitated upon exposure to the atmosphere. (Since such carbonates are prone to form supersaturated solutions, precipitation may not occur even at the points designated.)

<sup>2</sup> *Orig. Com. 8th Intern. Congr. Appl. Chem.*, **1**, 217 (1912).

<sup>3</sup> E. T. Allen and V. H. Gottschalk, *Am. Chem. J.*, **24**, 292-304 (1900); Hess and Campbell, *THIS JOURNAL*, **21**, 776 (1899); C. F. Cross, *Chem. News*, **39**, 161 (1879).

<sup>4</sup> F. M. G. Johnson, *THIS JOURNAL*, **34**, 911 (1912).

have shown that in common with most substances capable of absorbing moisture (even those not intrinsically hygroscopic) recently ignited  $\text{Al}_2\text{O}_3$  absorbs within the first ten minutes' exposure to the atmosphere a large proportion of the water which it will absorb in twenty-four hours. Since, as frequently pointed out, the atmosphere in an ordinary desiccator which has recently been opened, is not greatly different from the atmosphere prevailing in the room, it is obvious that the all too common practice of placing in a desiccator ignited precipitates such as  $\text{Al}_2\text{O}_3$ , in uncovered crucibles, is likely to lead to even greater errors than are involved during the period required for rapid weighing. That a well fitting cover on a platinum crucible is efficient in preventing rapid absorption of moisture in the desiccator or on the balance, has been frequently demonstrated. Thus a crucible containing 0.10 g. ignited  $\text{Al}_2\text{O}_3$ , which when allowed to stand covered upon the balance, showed no appreciable change in weight in five minutes; gained as much as 0.0010 g. when uncovered for five minutes. For any accurate work in the determination of alumina, therefore, and especially in any experiments designed to test the temperature and period required for the ignition of such substances, it is absolutely essential that the crucible be well covered both in the desiccator and upon the balance.

## 2. Temperature and Time of Ignition.

Directions for the ignition of alumina<sup>1</sup> have usually prescribed blasting for periods varying from ten to thirty minutes, followed by successive short periods till constant weight is secured. While it is evident that in order to expel the last traces of moisture from such a precipitate, originally in a gelatinous condition, the use of a high temperature is desirable, it may be readily shown that long blasting is not necessary, at least for precipitates up to 0.2 g.  $\text{Al}_2\text{O}_3$ . In numerous experiments with 0.1 g.  $\text{Al}_2\text{O}_3$  the total loss in weight produced by various periods of blasting following the first five minutes' blasting, was less than 0.0002 g. In order to show conclusively that dehydration is complete after five or ten minutes' blasting (at a temperature from  $1100^\circ$  to  $1150^\circ$ ), a covered crucible (of especially pure platinum) containing 0.7 g.  $\text{Al}_2\text{O}_3$ , derived from three precipitates each of which had been blasted for five minutes, was again blasted for five minutes, and placed in a vacuum sulfuric acid desiccator, which was quickly exhausted. After cooling, the crucible was quickly weighed (against a tared crucible) and was then heated for three periods of ten minutes each to a temperature of  $1440^\circ$  to  $1460^\circ$  in an electric furnace.<sup>2</sup>

<sup>1</sup> H. Moissan, *Compt. rend.*, 121, 851 (1895); W. H. Daudt, *J. Ind. Eng. Chem.*, 7, 847 (1915); P. H. Walker and J. B. Wilson, *Chem. Eng.*, 16, 159 (1912), and numerous text books.

<sup>2</sup> Thanks are due to Messrs. R. B. Sosman and J. C. Hostetter of the Geophysical Laboratory for assisting in these high temperature experiments (in 1912).

The results of the experiment were as follows:

TABLE II.  
Ignition of  $\text{Al}_2\text{O}_3$ .

	Weight against tare. Grams.
Empty crucible.....	3.1665 g.
Including $\text{Al}_2\text{O}_3$ (previously blasted but exposed in transfer) ..	3.8953
After five minutes' blasting.....	3.8943
Weight of $\text{Al}_2\text{O}_3$ .....	0.7278
After 10 minutes at $1440-1460^\circ$ .....	3.8943
Additional 10 minutes at $1440-1460^\circ$ .....	3.8941
Additional 10 minutes at $1440-1460^\circ$ .....	3.8940
Weight of empty crucible after brushing out precipitate ...	3.1662
Weight of $\text{Al}_2\text{O}_3$ after heating.....	0.7278

From these results it is evident that, making allowance for the loss in weight of the platinum crucible (0.0003 g.), exposure to a temperature of over  $1400^\circ$ , produced no appreciable change in weight of  $\text{Al}_2\text{O}_3$  previously blasted for not over fifteen minutes.

From these results it is apparent that the continued losses in weight noted by some authors upon successive blastings of  $\text{Al}_2\text{O}_3$  were probably due, not to further dehydration of the precipitate, but to losses in weight of the crucibles (which in commercial platinum may be quite appreciable); or, in case the crucibles were not covered while in the desiccator and on the balance, to a decrease in the hygroscopicity of the precipitate. In other words, at no time was the true anhydrous weight obtained, but always a weight including some amount of absorbed moisture, which amount decreases (and may become almost negligible) after the precipitate has been heated to high temperatures for a considerable period. Owing to the frequent failure to mention whether the crucibles were covered during the ignition and weighing, it is impossible to determine in which cases the above criticism applies. Such omissions indicate, however, a lack of appreciation of the importance of covering the crucibles.

### 3. *Effect of Ammonium Chloride upon the Ignition.*

The still prevalent misconception that when aluminium hydroxide containing ammonium chloride is ignited, there is loss of aluminium, dates back at least to 1875.<sup>1</sup> It has been disproven so frequently<sup>2</sup> that it would be superfluous to dwell upon it were it not for the fact that it is still referred to in recent text books. The following experiments, while probably not essential to disprove this conception, are perhaps of interest in still further demonstrating the absence of such an effect. Measured portions of a pure  $\text{AlCl}_3$  solution were evaporated to small volumes in

<sup>1</sup> C. R. Fresenius, "Quantitative Analysis," 6 Ger. edition (1875).

<sup>2</sup> W. F. Hillebrand, U. S. Geol. Survey, *Bull.* 422, 99 (1910); Allen and Gottschalk, *Am. Chem. J.*, 24, 292-304 (1900); W. H. Daudt, *J. Ind. Eng. Chem.*, 7, 847 (1915).

weighed platinum crucibles, after which pure ammonia in slight excess was added. Evaporation was continued to dryness and the residues were heated till expulsion of all ammonium salts, and finally blasted and weighed. The results, together with those obtained by the method of precipitation, etc., recommended below (which had been found to give accurate results with metallic aluminium) are shown in Table III.

TABLE III.  
Effect of Ammonium Chloride upon Ignition.

Method.	Direct evaporation.		Precipitation.			
$\text{Al}_2\text{O}_3$ from 50 cc. $\text{AlCl}_3$ .....	0.0998	0.0997	0.1002	0.1001	0.1000	0.0999

From Table III it may be seen that in Expts. 1 and 2, where the aluminium hydroxide was certainly in very intimate contact with an excess of ammonium chloride, any loss of aluminium by volatilization was so small as to be negligible. Moreover, the weights in the last four experiments include corrections for the filter ash, and for known small impurities in the reagents and water, and therefore are probably somewhat less accurate than those obtained by direct evaporation.

### VIII. Procedure Recommended.

From the foregoing considerations the following conditions are recommended for the determination of aluminium hydroxide: To the solution containing at least 5 g. of ammonium chloride per 200 cc. of solution (or an equivalent amount of hydrochloric acid) add a few drops of methyl red (0.2% alcoholic solution) and heat just to boiling. Carefully add dilute ammonium hydroxide dropwise until the color of the solution changes to a distinct yellow. Boil the solution for one to two minutes, and filter at once. Wash the precipitate thoroughly with hot 2% ammonium chloride (or nitrate) solution. Ignite in a platinum crucible, and after the carbon is all burned off blast for five minutes, cover the crucible and place it in a desiccator till cool. Weigh (covered) as rapidly as possible. A second blasting of five minutes is desirable, especially as it permits a more rapid weighing, and consequently probably more accurate results.

### IX. Confirmatory Experiments.

A weakness of many of the published researches upon the determination of aluminium is the lack of suitable standards by which to test the proposed methods. The use for this purpose of hydrated salts of possibly uncertain hydration, such as the alums, is not to be recommended for accurate work, and in the few cases where metallic aluminium has been used, no detailed evidence of the purity has been presented. The following few experiments, though by no means exhaustive, show that the method just described will yield results accurate to at least one part in three hundred and probably better.

Two samples of the purest aluminium that could be obtained in 1912 from the Aluminum Company of American were analyzed by the methods described by J. O. Handy,<sup>1</sup> yielding the following results for the only elements that could be detected:

TABLE IV.  
Analysis of Aluminium.

Sample.	A.	B.
Silicon.....	0.13%	0.16%
Copper.....	0.01	0.01
Iron.....	0.25	0.17
Aluminium (diff.).....	99.61	99.66

Weighed portions (about 1.3 g.) of these samples were dissolved in hydrochloric acid and the solutions were oxidized with a small amount of nitric acid, and filtered to remove silicon. The filtrates were diluted to measured volumes and aliquots used for the determination of aluminium as above described, about 0.25 g. of  $\text{Al}_2\text{O}_3$  being weighed in each determination. The ammonia was redistilled and all reagents carefully tested and found free from appreciable contamination. The weights of precipitates were corrected for the filter ash, and for the amount of  $\text{Fe}_2\text{O}_3$  corresponding to the iron found by the previous analysis. The results are shown in Table V.<sup>2</sup>

TABLE V.  
Aluminium Determination in Metallic Aluminium.

Expt.	Sample.	Weight of Sample. Gram.	Found.		Al %.	
			$\text{Al}_2\text{O}_3$ Gram.	Al. Gram.	Found.	By diff.
1.....	A	0.12980	0.2445	0.12967	99.90	99.61
2.....	A	0.12980	0.2443	0.12956	99.82	...
3.....	B	0.12884	0.2428	0.12877	99.95	99.66

### X. Conclusions.

From the above experiments the following conclusions may be drawn, many of which simply confirm those of previous investigators:

(1) From observations made with a hydrogen electrode and with suitable indicators, it was found that the precipitation of aluminium

<sup>1</sup> THIS JOURNAL, 18, 768 (1896).

<sup>2</sup> In calculating the weight of aluminium present in the  $\text{Al}_2\text{O}_3$  the 1916 atomic weight of Al = 27.1, has been used. It is at least interesting, though probably not significant with so few experiments, to note that if the round atomic weight 27 be used for Al, the values for % Al found, become, respectively, 99.73 and 99.67 for A, and 99.78 for B, i. e., approaching the amount found by difference, well within the experiment limit. No probable source of error in the determinations in Table V is likely to account for the existing discrepancies, amounting to from 0.0006 to 0.0008 g.  $\text{Al}_2\text{O}_3$ . More experiments are required to throw light upon these discrepancies. The point is merely mentioned as of interest in connection with the statement of F. W. Clarke ("Recalculation of the Atomic Weights," p. 268, 3rd edition (1910)) that "the atomic weight of aluminium needs reinvestigation."

hydroxide by ammonium hydroxide is complete when  $[H^+] = 10^{-6.5}$  to  $10^{-7.5}$ , points approximately defined by the color change of methyl red and of rosolic acid.

(2) The presence of ammonium chloride during precipitation is advantageous in limiting the alkalinity, and in coagulating the precipitate.

(3) Solutions of ammonium nitrate and chloride are equally satisfactory for washing the precipitate.

(4) The conditions of precipitation recommended are favorable for the simultaneous precipitation of aluminium and ferric hydroxides; and for their separation from calcium, strontium, barium, and magnesium.

(5) Crucibles containing ignited alumina should be kept covered in the desiccator and on the balance.

(6) For precipitates of from 0.1 to 0.2 g.  $Al_2O_3$ , five or ten minutes' blasting is sufficient.

(7) The presence of ammonium chloride during ignition causes no appreciable loss of alumina.

## THE ESTIMATION OF VANADIC ACID, AFTER REDUCTION BY METALLIC SILVER.

By GRAHAM EDGAR.

Received March 23, 1916.

Among the many reactions of vanadic acid to be found in the literature, that with metallic silver seems to have been almost overlooked by the numerous investigators who have studied the element vanadium. The only reference which the writer has been able to find bearing at all on this subject is the statement in a paper by Campbell and Griffin<sup>1</sup> that "silver, lead, copper and other elements were tried (as reducing agents on mixed uranyl and vanadyl solutions) but \* \* \* offered no advantages for this purpose." It is true that Perkins<sup>2</sup> reduced vanadic acid to the tetroxide by the action of hydriodic acid and metallic silver, but he considered that the function of the silver was merely that of absorbing the iodine set free in the reaction, and the possibility of any direct action between the silver and vanadic acid seems not to have been thought of.

That silver should be capable of reducing pentavalent vanadium to tetravalent could be predicted with a considerable degree of certainty by consideration of the values obtained by Rutter<sup>3</sup> for the oxidizing potentials of solutions of vanadic acid, and also from the fact that silver is

<sup>1</sup> *J. Ind. Eng. Chem.*, **1**, 661 (1909).

<sup>2</sup> *Am. J. Sci.*, [4] **29**, 540.

<sup>3</sup> *Z. anorg. Chem.*, **52**, 368 (1907).

capable of reducing ferric salts, which are less easily reduced than solutions of vanadic acid. That the reduction cannot proceed further than the tetravalent stage (as it does in the case where zinc, magnesium or aluminum is used as the reducing agent) could also be predicted from the fact that divalent and trivalent vanadium salts precipitate metallic silver from solutions of silver salts.<sup>1</sup> We should expect therefore that the reaction

should be strictly quantitative—an expectation which is fully confirmed by the results given in this paper.

The course of the reaction can obviously be measured in three ways: (a) from the loss in weight of the metallic silver (if a weighed excess is used to effect the reduction); (b) by estimation of the dissolved silver (for example by titration with standard  $\text{NH}_4\text{CNS}$  solution); and (c) by oxidimetric estimation of the reduced vanadium, say, with standard  $\text{KMnO}_4$ . Provided the reaction is strictly quantitative, any one or all of these methods might be used for the quantitative estimation of vanadium.

To test the validity of these conclusions a series of experiments was carried out to determine the conditions, if any, under which a quantitative reduction of pentavalent vanadium to tetravalent might be expected.

#### Reagents and Apparatus.

Solutions of pure sodium vanadate (free from chloride) were carefully standardized against  $\text{KMnO}_4$ , after reduction with sulfur dioxide, and also by the very accurate method of Holverscheid.<sup>2</sup>

Potassium permanganate, approximately 0.05 *N*, was standardized against sodium oxalate.

Ammonium thiocyanate, approximately 0.05 *N*, was standardized against 0.1 *N* silver nitrate.

Metallic silver was prepared by electrolysis of a silver nitrate solution, using a platinum anode enclosed in a porous cup, and a fine platinum wire suspended near the top of the solution, as cathode. Under these conditions if a moderately heavy current is passed through the solution the silver is deposited as a "bush" of very fine crystals which drop continually from the cathode to the bottom of the beaker, and which can be later removed by filtration. The finely divided crystals were boiled with dilute sulfuric acid in order to remove any impurities which might be soluble in this medium, and were then filtered off through an alundum crucible, washed, and ignited at low red heat. In certain of the preliminary experiments other forms of silver were used, for instance, that formed by precipitation by zinc dust from dilute silver nitrate solution, or by

<sup>1</sup> Rutter, *Loc. cit.*

<sup>2</sup> *Inaug. Diss.*, Berlin, 1890.

igniting silver oxide, or in one case a spiral of pure fine silver wire. Mention is made of this in later discussion.

All pipets and burets used had been calibrated carefully and carried certificates of accuracy, and the greatest care was taken in making all measurements and readings. In all titrations the amount of the reagent necessary to produce the color change of the end point was determined by "blank" experiments and the readings were corrected accordingly. The amount was usually between 0.03 and 0.05 cc.

### Experimental Results.

After certain preliminary experiments which will not be recorded here, a number of determinations were made as follows:

Carefully measured portions of a standard solution of sodium vanadate were acidified with about 2 cc. of conc.  $\text{H}_2\text{SO}_4$ , diluted to about 75 cc., and treated with 1 to 2 g. of metallic silver, the exact weight of which had been previously determined. The small flasks containing the solutions were then placed upon a quartz plate, and the solutions were boiled gently for twenty minutes, or in some cases for one-half hour. Usually the boiling was continued for about ten minutes after the appearance of the pure blue color which signifies practically complete reduction of the vanadium. The solutions were then filtered upon asbestos in weighed perforated porcelain crucibles, and the residue of silver was washed with hot water. The crucibles were then placed inside of a larger nickel crucible and heated therein for about one-half hour, the outer crucible being subjected to the full heat of a large Bunsen burner. Under these conditions the inner porcelain crucible is at very low red heat. After cooling in a desiccator the crucibles were weighed, and the loss of weight of the silver was calculated.

The filtrates from the silver, containing all of the vanadium in the tetravalent condition, together with the dissolved silver, were titrated hot with 0.05  $N$   $\text{KMnO}_4$ . At the completion of this titration the solutions were cooled and titrated for silver with 0.05  $N$   $\text{NH}_4\text{CNS}$ , after the addition of ferric alum as indicator.

<sup>1</sup> Reduced with silver wire; see below.

The amount of vanadic acid present was calculated (a) from the loss in weight of the metallic silver, (b) from the permanganate titration, and (c) from the silver equivalent to the thiocyanate titration. The results given in Table I show that the reaction is strictly quantitative, and that not only the gravimetric method, but also the volumetric ones are very accurate measures of the amount of vanadic acid present.

The value of these results is obvious. They afford an accurate and simple *gravimetric* method for the estimation of vanadium, which can in the same operation be checked by *two volumetric* estimations with very little additional trouble. Furthermore, if the gravimetric estimation is not desired, the operation can be very materially shortened and still permit the employment of the two volumetric estimations. In Table II are given the results of experiments in which the acid vanadate solutions were heated as above with unweighed amounts of metallic silver, filtered through paper or asbestos, and the filtrates titrated first with permanganate and then with thiocyanate as in the first set of experiments.

TABLE II.

4	0.1260	19.48	0.1259	28.10	0.1260	-0.00005
5	0.1260	19.50	0.1261	28.15	0.1262	+0.00015
6	0.1260	19.50	0.1261	28.10	0.1260	+0.00005

These results show that vanadic acid can be very accurately determined by titration with permanganate or thiocyanate, or both, after reduction by metallic silver.

**Discussion of Factors Influencing the Completion of the Reaction** (based partially upon the above experiments and partially upon the preliminary experiments, not here recorded).

**Time.**—The time necessary for complete reduction varied, naturally, with the total amount of vanadium present, with the amount of silver used, and with its state of subdivision. With as much as 2 g. of finely divided crystalline silver complete reduction of about 0.1200 g. of vanadic acid occurred after ten minutes' boiling. On the other hand, when only 0.5 g. of silver was used, reduction in some cases was incomplete after as much as one-half hour's boiling. The influence of the state of subdivision of the silver was shown by an experiment in which about 1.5 g. of fine silver wire was used as the reducing agent. In this case the gravimetric and volumetric estimation (Table I, No. 7) showed that reduction was complete, but this was only after an hour's boiling. The best prac-

tice seemed to be to continue boiling gently for about ten minutes after the solution had become a pure blue in color. Longer boiling, though unnecessary, is not harmful. Certain of the preliminary experiments showed that heating on the water bath for about two hours could usually be substituted for the boiling, but the results were not quite so certain.

**Preparation of Silver.**—No appreciable difference could be observed in the action of electrolytic silver, silver reduced by zinc, and silver prepared by heating the oxide, provided the purity was the same, and provided that preliminary treatment with dilute sulfuric acid was given. The electrolytic silver is, however, recommended as being more apt to be pure, and as giving somewhat more uniform results. It is easily prepared by the method given above.

**Acidity.**—The acidity of the solutions was varied between 0.5 cc. and 3 cc. of conc.  $\text{H}_2\text{SO}_4$  in a total volume of 75 cc. No very marked differences in behavior were observed, but somewhat more uniform results were obtained when 1 to 2 cc. in 75 cc. were used.

The reduction takes place readily when hydrochloric acid is used instead of sulfuric. In this case the dissolved silver is precipitated as chloride, and the vanadic acid present may be calculated from the *increase* in weight of the silver used for the reduction, as well as by permanganate titration of the filtrate. The gravimetric method is not quite so accurate as when loss of weight is determined, for, of course, the increase of weight due to chlorine is only about one-third of the decrease in weight caused by the solution of an equivalent amount of silver. Furthermore, the permanganate titration in the hot solution containing hydrochloric acid is not so accurate as in the presence of sulfuric acid alone, even when all precautions are observed. If it is desired, however, to determine vanadium in a solution containing hydrochloric acid, the silver reduction followed by permanganate titration may be used with a fair degree of accuracy. A better method is to remove the hydrochloric acid with silver sulfate in slight excess, and then determine vanadium as described above for solutions containing sulfuric acid. Either the gravimetric method or the permanganate titration may be employed, and even the thiocyanate titration also, provided a blank is run to determine the silver already present.

Nitric acid must not be present, for obvious reasons, nor any other substance acted upon by finely divided silver under the conditions of the experiment. The application of the reaction to the determination of vanadium in technical products, and in the presence of other substances, will be the subject of further investigation.

**Filtration.**—Where the gravimetric method is to be carried out, filtra-

tion through asbestos in a perforated porcelain crucible (or through alundum) is far preferable to filtration through paper. Where only the volumetric processes are to be carried out, filtration through paper is probably more convenient. It is even possible to wash the silver residue by decantation entirely, but filtration in this particular case is so rapid that decantation gains no time, and there is always the risk that fine particles of silver may be carried into the solution to be titrated, and thus spoil the determination.

**Accuracy.**—The accuracy with which duplication of results can be obtained is very unusual. This is especially true of the permanganate titration, where the writer had had as many as six consecutive titrations show no readable difference in the volume of permanganate used. Slightly greater variations were obtained in the thiocyanate titration, but here also the results are excellent. The writer has had experience with nearly all of the standard methods for the estimation of vanadium, and has obtained better results with the method proposed here than with any other of his experience. The fact that three check determinations may be made on the same solution should make the method admirably adapted to the exact standardization of vanadic acid solutions, or to other cases where high accuracy is desired.

Another useful feature of the method is the opportunity which it offers for the gravimetric standardization of permanganate solutions against metallic silver, or of comparing permanganate and thiocyanate solutions against one another. For this purpose complete reduction of the vanadic acid is not necessary, as the three factors, loss of weight of silver, permanganate titration, and thiocyanate titration are always strictly proportional, regardless of the extent to which the vanadium is reduced.

### Summary.

Vanadium is quantitatively reduced from the pentavalent to the tetravalent condition by metallic silver in acid solution under proper conditions.

The reaction may be used to determine vanadium (a) gravimetrically, from the loss in weight of the silver; (b) oxidimetrically, by titration with standard potassium permanganate; or (c) by titration of the dissolved silver with ammonium thiocyanate. All of these operations may be carried out on the same solution, and serve to check each other.

The results are of the highest order of accuracy.

The reactions may be also used for the standardization of permanganate solutions against silver, and of permanganate and thiocyanate solutions against each other.

## CONSTITUTION OF CHROMIC ACID.

[PART I.]

BY ASWINI KUMAR DATTA AND NILRATAN DHAR.

Received March 21, 1916.

From observations on the depression of the freezing point of aqueous solutions of chromium trioxide and the colorimetric study of the watery solutions of chromic acid, chromates and dichromates, and from the results of electrical conductivity measurements, Ostwald concludes that chromic acid solutions contain the strong acid  $\text{H}_2\text{Cr}_2\text{O}_7$  which forms neutral salts not appreciably hydrolyzed in aqueous solution. Costa,<sup>1</sup> from ebullioscopic measurements of chromic acid in aqueous solutions, shows that solutions not too concentrated contain the acid  $\text{H}_2\text{Cr}_2\text{O}_7$ . Spitalsky<sup>2</sup> arrived at similar conclusions from a study of the concentration of  $\text{H}^+$  in solutions of free chromic acid. Sabatier<sup>3</sup> tried to establish the identity of the spectra of chromic acid and dichromates, but no definite conclusion can be drawn from this work.

Sherril,<sup>4</sup> from an elaborate and careful study, considers that dilute solutions of  $\text{K}_2\text{Cr}_2\text{O}_7$  contain almost exclusively the ions  $2\text{K}^+$  and  $\text{Cr}_2\text{O}_7^{--}$  but that strong solutions of  $\text{K}_2\text{Cr}_2\text{O}_7$  are slightly acid owing to slight hydrolysis. Evidently Sherril has tried to amalgamate the two opposing views.<sup>5</sup>

Dubrisay<sup>6</sup> has shown that chromic acid differs from a strong dibasic acid, such as sulfuric acid, in exhibiting a constant surface tension only until the first acid function is neutralized, after which the surface tension decreases gradually but slightly until the second is neutralized.

Walden,<sup>7</sup> from conductivity measurements, adduces strong reasons in favor of the formula  $\text{H}_2\text{CrO}_4$ . Abegg and Cox<sup>8</sup> took the same view as that taken by Walden and they also add further reasons in support of this formula.

The present investigation is an attempt to assist in the solution of the problem by a study of further physical properties of chromium trioxide ( $\text{CrO}_3$ ) and  $\text{R}_2\text{Cr}_2\text{O}_7$  in solution.

## Molecular Volume in Solution.

If  $m$  is the molecular weight of a dissolved substance in grams,  $l$  the quantity of solvent which is present for every mol of solute,  $d$  the density

<sup>1</sup> *Gaz.* 36 (1906).

<sup>2</sup> *Z. anorg. Chem.*, 54, 265 (1907).

<sup>3</sup> *Compt. rend.*, 103, 49.

<sup>4</sup> *THIS JOURNAL*, 29, 1614 (1907).

<sup>5</sup> See also Dehn, *THIS JOURNAL*, 36, 829 (1914) for a colorimetric investigation of the chromates.

<sup>6</sup> *Compt. rend.*, 156, 1902 (1913).

<sup>7</sup> *Z. physik. Chem.*, 2, 70 (1888).

<sup>8</sup> *Ibid.*, 48, 725 (1904).

of the solvent and  $d$ , the density of the solution, the "Molecular solution volume",  $V_m$  is related to these as follows:

$$sV_m = \frac{m + l}{d_s} - \frac{l}{d}$$

From the molecular solution volume of a large number of substances, Traube calculated the atomic volume of the elements and the volume effects of a few of the chief modifications of structure and he also deduced from his extensive work a process for ascertaining the molecular weight of a substance in dilute aqueous solution. For dissolved substances we have the relation

$${}_sV_m = \Sigma nC + \phi_s,$$

where  $V_m$  is the molecular solution volume of the substance and  $\phi_s$  the molecular solution co-volume, which is approximately constant. In calculating  $\Sigma nC$  the atomic and structural constants for the substance in solution are used and, further, if the substance is an electrolyte, allowance is made for dissociation. This method has been successfully used in ascertaining the association factor of many substances.

The two possible formulas for chromic acid are  $\text{H}_2\text{CrO}_4$  and  $\text{H}_2\text{Cr}_2\text{O}_7$ . Now, all the above substances are strong electrolytes, chromic acid being a strong acid as has been determined from conductivity measurements and its chemical behavior.  $\text{H}_2\text{CrO}_4$  and  $\text{K}_2\text{CrO}_4$  are evidently of similar structure and so are  $\text{K}_2\text{Cr}_2\text{O}_7$  and  $\text{H}_2\text{Cr}_2\text{O}_7$ , and the difference between the molecular solution volume of  $\text{K}_2\text{CrO}_4$  and chromic acid, on the supposition that its formula is  $\text{H}_2\text{CrO}_4$ , should be equal to the difference between the solution volume of 2 atoms of potassium and 2 atoms of hydrogen. This also would be the difference between the molecular solution volume of  $\text{K}_2\text{Cr}_2\text{O}_7$  and chromic acid if its formula be  $\text{H}_2\text{Cr}_2\text{O}_7$ . It was found that the relation stated above holds good only when we take the formula for chromic acid as  $\text{H}_2\text{Cr}_2\text{O}_7$ .

TABLE I.  
Chromic Acid.

The materials used were prepared in several ways and carefully purified by repeated crystallization and were dissolved in "Conductivity water" and kept in "Resistance glass" bottles. The strength of chromic acid was ascertained by adding excess of pure KI and titrating the iodine by

standard sodium thiosulfate. The density was determined by means of a Sprengel pyknometer as modified by Ostwald, following the details as given by him. The densities recorded above are the means of three determinations, agreeing to the fifth decimal place.

TABLE II.

Potassium dichromate.			Potassium chromate.		
Density.	Salt per cc. (g.).	$sV_m$ .	Density.	Salt per cc. (g.).	$sV_m$ .

Mean, 89.7			Mean, 41.0		

Traube found the atomic volume, in solution, of hydrogen = 3.1 and of sodium = 1.8. He does not seem to have calculated that for potassium. We calculated the atomic volume in solution of potassium from the following data taken from "Physikalisch-chemische Tabellen":<sup>1</sup>

TABLE III.

Sodium Chloride.			Potassium Chloride.

1.1164	0.01755	17.7	1.1317	0.2238	27.4
Av., 17.6			Av., 28.0		

Now sodium chloride and potassium chloride are both salts of similar nature. Their "structural constants" and "allowance for ionization" may be taken to be equal. The difference between their molecular volumes in solution is evidently that between the atomic volume in solution (A) of one atom of potassium and one atom of sodium. The atomic volume in solution of potassium is therefore 28 ( $sV_m$  for KCl) — 17.6 ( $sV_m$  for NaCl) + 1.8 (A for Na) = 12.2. This atomic constant of potassium may also be deduced as follows:

Traube<sup>2</sup> found the atomic volume (A) in solution of chlorine to be 13.2. Therefore

$$28.0 = 13.2 + A \text{ (for K)} + x \quad (1)$$

$$17.6 = 13.2 + 1.8 \quad + x \quad (2)$$

$x$  is a constant dependent on the nature of the salt and is the same for both KCl and NaCl, they being salts of the same nature.

From (1) and (2) we get A (for K) = 12.2. The two results are identical, showing the validity of our assumptions. The atomic volume

<sup>1</sup> Landolt and Bornstein, p. 177.

<sup>2</sup> Loc. cit.

in solution of potassium can therefore be taken to be 12.2. The difference between the solution volume of 2 atoms of potassium and 2 atoms of hydrogen is therefore  $12.2 \times 2 - 3.1 \times 2 = 18.2$ . The molecular volume in solution of potassium dichromate as has been found is 89.7 and that of chromic acid on the supposition that its formula is  $\text{H}_2\text{Cr}_2\text{O}_7$  is 70.9. The difference is 18.8 in good agreement with the calculated number 18.2. The molecular volume in solution of potassium chromate is 41.0 and that of chromic acid on the supposition that its formula is  $\text{H}_2\text{CrO}_4$  is 44. The difference is  $-3$  instead of  $+18.2$ . We are thus lead to conclude that formula for chromic acid is  $\text{H}_2\text{Cr}_2\text{O}_7$  and not  $\text{H}_2\text{CrO}_4$ . The above line of reasoning seems to be clear and satisfactorily confirmed by experimental evidence. But we should mention here that it has been found that this method does not always yield the right result. Gioletti<sup>1</sup> has applied the method to some tautomeric compounds, and on the whole the results are not very encouraging. Acetoacetic ester has the molecular volume 126.9, while the calculated<sup>2</sup> volume for the enolic form is 127.9 and that for the ketonic structure is 132.8. Accordingly it might be supposed that the sample consisted entirely of the enolic tautomeride; but this is contrary to chemical experience and to the evidence from other physical sources.

### Refractivity.

Refractivity is both additive and constitutive.<sup>3</sup> The molecular refraction of a compound is the sum of the refraction equivalents of the elements which enter into the compounds, modified by the manner of combination. So by an examination of their refractive equivalent of a substance we may gain a knowledge about the molecular condition of the substance.

Molecular refractivity of a solid electrolyte is slightly altered by solution in water. The behavior of different salts is not uniform, some increase and others decrease in refractivity on passing into solution. The effect of dilution is pronounced with concentrated solution. It tends to be constant with dilution and in a moderately dilute solution it becomes fairly constant.

We determined the molecular refractivity of various solutions of chromates, dichromates and chromic acid by Pulfrich's refractometer, using a sodium flame as the source of light. A certain amount of the substance was dissolved in water and the refractive index and density of the solution were taken. From this the refractive equivalent,  $n - 1/d = m$  was calculated, where  $n$  is the refractive coefficient,  $d$  the density and  $m$

<sup>1</sup> *Gazz. chim. ital.*, 34, 208 (1904).

<sup>2</sup> Traube, *Ber.*, 29, 1715 (1896).

<sup>3</sup> Gladstone, *Proc. Roy. Soc.*, 439 (1868); 60, 140 (1896); Gladstone and Hilbert, *Trans. Chem. Soc.*, 67, 831 (1895).

the molecular weight of the compound. The refractive equivalent of the dissolved salt is obtained by deducting from the refractive equivalent of a solution of the form  $s + p\text{H}_2\text{O}$ , where  $s$  signifies one molecule of the salt—the value which corresponds with  $p \times \text{H}_2\text{O}$ . That is the refractive equivalent of the salt =  $\frac{u-1}{d}(m+x) - \frac{u'-1}{d'}x$ , where  $u$  is the refractive coefficient of the salt solution,  $d$  its density,  $m$  the molecular weight of the salt,  $x$  the weight of the solvent containing the gram molecular weight of the salt,  $u'$  the refractive coefficient of the solvent and  $d'$  its density.

Av., 82.6

In the present case the solvent is water, its density is taken to be unity at the temperature of the experiments, which was about  $26^\circ$ . The density of the solutions is of course determined at the same temperature. The refractivity of water used in the solution was observed separately each time

the refractivity of the solution was observed. It was found that the refractivity of the water varied from day to day very slightly, the maximum deviation being 1' (one minute) in the reading of the scale of the instrument which affected the refractive coefficient only in the fifth decimal place. This slight variation was evidently due to slight change of temperature and partly to errors of experiments.

Gladstone and others have found the refractive equivalent of potassium atom = 8.1 and of hydrogen in acids = 3.5. The refractive equivalent of hydrogen in water and other nonionizable substances is 1.5, but the value for hydrogen in strong acids is 3.5.<sup>1</sup> The difference between the refractive equivalents of 2 atoms of potassium and two atoms of hydrogen is therefore  $16.2 - 7 = 9.2$ . By similar lines of reasoning as indicated in the case of molecular solution volume we can expect the difference between the refractive equivalents of potassium dichromate and chromic acid, on the supposition that its formula is  $H_2Cr_2O_7$ , to be 9.2. By actual experiments we find the difference to be  $82.6 - 73.2 = 9.4$ . If the formula of chromic acid be  $H_2CrO_4$  we should get the same difference between the refractive equivalents of potassium chromate and chromic acid ( $H_2CrO_4$ ). By experiment we find it  $52.2 - 39.5 = 12.7$  in place of 9.2. The formula of chromic acid is therefore  $H_2Cr_2O_7$  and not  $H_2CrO_4$ . This is also the conclusion arrived at from the study of volume relations.

Thus we see that two most important physical properties of chromic acid in solution are in support of the formula  $H_2Cr_2O_7$ , which also seems to be the more probable one from various other investigations.

In a subsequent paper, some other physical properties will be discussed.

### NOTE.

**A Bottle for the Iodimetric Titration of Copper.**—Since L. W. Andrews<sup>2</sup> first described the use of iodate as a substitute for many iodimetric determinations, the method has been extended and is finding additional uses constantly. In technical practice particularly, the application to copper ores as described by Jamieson, Levy and Wells,<sup>3</sup> and by Brostrom<sup>4</sup> is finding much favor; in this method, there is formed hydrocyanic acid—a feature that militates against the use of the original shaking bottle as described by Andrews because of the pressure developed in shaking and the consequent forcible ejection of particles of liquid on removing the

<sup>1</sup> LeBlanc, *Z. physik. Chem.*, 4 (1889); Gladstone, *Phil. Mag.*, 15 (1870).

<sup>2</sup> THIS JOURNAL, 25, 756 (1903).

<sup>3</sup> *Ibid.*, 30, 760 (1908).

<sup>4</sup> *Eng. Mining J.*, 98, 215 (1914).

stopper between additions of iodate: on the other hand, the use of a simple open Erlenmeyer, as used in the Southwest copper district, limits more than desirable the freedom in shaking: both difficulties may be overcome by replacing the glass stopper by a two-hole rubber stopper, through which pass two glass tubes, 5-6 mm. in diameter and about 8 cm. long, one of the tubes being widened at the top to serve as an inlet for the iodate solution, the other serving as an outlet for vapor, their length preventing loss by ejection during shaking.

With a little additional trouble, a somewhat more efficient modification may be constructed: this is illustrated in the accompanying sketch. The tube is 7-8 mm. in diameter, flared above, narrowed and curved below, and provided with a blowhole just below the cork. This side hole acts not only as the pressure vent but also serves the purpose of washing the last drop of iodate down during the shaking without the use of a wash bottle.

This bottle has been in constant use by students for copper ore analyses in this laboratory for over a year and found quite satisfactory: besides its convenience, it saves the time required in removing the stopper or in shaking so very cautiously. The only objectionable feature is the action of chloroform or carbon tetrachloride on the rubber stopper if allowed to stand overnight: during titration the stopper is protected by an aqueous film and shows no deterioration even after long use.

## THE ADDITION COMPOUNDS OF PHENOLS WITH ORGANIC ACIDS.

BY JAMES KENDALL.

Received May 20, 1916.

It has been shown by the author in a recent communication<sup>1</sup> that *strong* organic acids (such as trichloroacetic acid) will combine directly with

<sup>1</sup> Kendall, *THIS JOURNAL*, 36, 1722 (1914).

weak organic acids (such as benzoic acid) to form equimolecular addition products. Compounds of this type are relatively unstable, in so far as they dissociate into their components to a considerable extent on fusion, but they can be readily isolated and identified by means of the freezing-point method described in a previous paper.<sup>1</sup> The stability of the addition products, as indicated by the curves obtained, increases with the difference between the acidic strengths of the two components.

The formation of compounds of this nature has been assumed to be due to the presence of the basic (or unsaturated) group  $\text{>C} = \text{O}^\pm$  in the weak acid. The oxygen atom in this group is potentially quadri-valent, and in the presence of a sufficiently strong acid the acidic properties of the weak organic acid are suppressed to such a degree that the basic nature of the group comes into prominence and an oxonium salt formation is obtained. The reaction is considered to be ionic and to take place as follows:

A great deal of evidence in favor of these views has been collected in a series of researches on organic substances of various types.<sup>2</sup>

The extension of this method of investigation to systems of the general type phenol-acid has seemed of importance to the author for several reasons. In the first place, most phenols belong to the class of weak organic acids and might therefore be expected to resemble them in exhibiting basic properties in the presence of a strong acid, with the consequent formation of oxonium salts analogous to those already described. Since, further, phenols in general are much more weakly acidic than the weak acids previously investigated (*e. g.*, benzoic acid); any addition products obtained should prove to be more stable in character, and less dissociated into their components in the liquid state.<sup>3</sup>

In the second place, the isolation and examination of addition compounds of the type phenol-acid are of interest because of the probability that the formation of such compounds constitutes an intermediate stage in the series of reactions involved in the direct production of phenolic esters of organic acids.<sup>4</sup> The general equation

<sup>1</sup> Kendall, *THIS JOURNAL*, **36**, 1222 (1914).

<sup>2</sup> Kendall and Carpenter, *Ibid.*, **36**, 2498 (1914); Kendall and Gibbons, *Ibid.*, **37**, 149 (1915).

<sup>3</sup> The validity of this assumption is discussed fully later (page 1320).

<sup>4</sup> Meuschutkin, *Ann.*, **197**, 220 (1879). The extent of the esterification, when equilibrium is reached, is only small (as in the case of the tertiary alcohols); hence the method is not available for the preparation of phenolic esters unless some dehydrating agent is added.

(where R is the aryl radical) merely shows the initial and end products, and gives no indication as to the mechanism of the reaction. The present investigation is thus immediately connected with the previous work of Kendall and Carpenter,<sup>1</sup> in which it was shown that phenols form with sulfuric acid stable addition compounds which may be regarded as intermediate products in the process of sulfonation.

In the complete examination of the field covered by systems of the general type phenol-acid, another point which deserves investigation is encountered. Phenols exhibit among themselves just as considerable a variation in acidic strength as do organic acids, consequently it is possible to construct systems which may be expected to behave quite differently from those already described. A convenient method of increasing the acidity of a phenol is to introduce nitro groups into the benzene nucleus. The effect of this will be to diminish the stability of the oxonium compounds obtained with strong acids, or even to prevent the formation of addition products altogether. By continued introduction of nitro groups into the nucleus we can obtain phenols (for example, picric acid) which are, indeed, quite as strongly acidic as the strongest organic acids. Such phenols may be expected to function similarly to *strong* acids, and to give oxonium compound formation both with *weak* acids and also with *weak* phenols. We can, therefore, by suitable variation of the acidic strengths of our two components, obtain most diverse examples of the general type, and these may be predicted to exhibit very different behavior when examined by the freezing-point curve method.

In the experiments tabulated below, this method has been employed in order to study the whole field, the acidic strengths of both phenols and acids being varied as widely as possible. As a typical strong acid, trichloroacetic acid has been chosen; it is easily obtained pure, has a convenient point of fusion, and has already been extensively used in previous work on addition compounds.<sup>2</sup> As a typical strong phenol, picric acid was selected; it is the simplest of its class and the most readily obtainable. Its disadvantages are a high melting point (which is unfavorable for the isolation of addition products, since their stability decreases with rise of temperature), the formation of dark-colored solutions with weak phenols (in which it is extremely difficult to detect the appearance or disappearance of crystals), and its highly explosive nature. The friction involved in the stirring of a molten mass largely consisting of picric acid constituted a source of constant danger, nevertheless it was found possible to complete the systems required with only a few minor accidents.

<sup>1</sup> Kendall and Carpenter, *Loc. cit.*

<sup>2</sup> Hence the results obtained here are directly comparable with those of previous papers. (See page 1317.)

The weak acids and phenols included in the investigation, with their ionization constants in aqueous solution at 25°, are given below.

Acids.	K.	Phenols.	K.
Acetic <sup>1</sup>	$1.85 \times 10^{-5}$	Phenol <sup>2</sup>	$1.15 \times 10^{-10}$
<i>o</i> -Toluic <sup>3</sup>	$12.0 \times 10^{-5}$	<i>o</i> -Cresol <sup>3</sup>	$0.63 \times 10^{-10}$
<i>m</i> -Toluic <sup>3</sup>	$5.14 \times 10^{-5}$	<i>m</i> -Cresol <sup>3</sup>	$0.98 \times 10^{-10}$
$\alpha$ -Toluic <sup>3</sup>	$5.56 \times 10^{-5}$	<i>p</i> -Cresol <sup>3</sup>	$0.67 \times 10^{-10}$
Chloroacetic <sup>3</sup>	$1.55 \times 10^{-3}$	Thymol <sup>2</sup>	$0.32 \times 10^{-10}$
Trichloroacetic <sup>3</sup>	$2.57 \times 10^{-1}$	<i>o</i> -Nitrophenol <sup>4</sup>	$6.8 \times 10^{-8}$
		<i>m</i> -Nitrophenol <sup>4</sup>	$1.0 \times 10^{-8}$
		<i>p</i> -Nitrophenol <sup>4</sup>	$6.5 \times 10^{-8}$
		$\alpha$ -Naphthol <sup>5</sup>	$1.0 \times 10^{-8}$
		$\beta$ -Naphthol	not determined
		Picric acid <sup>6</sup>	$2.52 \times 10^{-1}$

The ionization constants for the two strong acids employed, which are appended for comparison, are calculated for the concentration  $v = 32$ . The values given would, of course, change considerably with dilution, but the relative strengths of the two acids remain nearly constant. In alcohol, picric is the stronger acid<sup>7</sup> of the two.

The acids and phenols employed were either Kahlbaum specimens of a satisfactory degree of purity (as evidenced by the melting point) or were specially purified by recrystallization from a suitable solvent.

The experimental method followed was exactly as described in the previous papers of this series, the freezing-point curve of the two-component system being determined and all the desired information regarding the existence and stability of the addition products obtained being derived directly therefrom. In the tables below, T denotes the temperature of incipient solidification<sup>8</sup> of the mixtures, the compositions of which are expressed in molecular percentages. Examples of the curves obtained are reproduced in the accompanying diagram.

For convenience, the various types of systems examined from which oxonium salt formation may be expected are given under three divisions:

- I. Systems: weak phenol-strong acid (Tables 1-10).
- II. Systems: weak phenol-strong phenol (Tables 11-15).
- III. Systems: weak acid-strong phenol (Tables 16-19).

The fourth possible compound-forming type, systems: weak acid-strong acid, has already been fully investigated in a previous communication.<sup>9</sup>

- I. Trichloroacetic acid-phenol. Subtract  $130^{\circ}$  from temperature scale.
- II. Picric acid-*m*-cresol. Subtract  $50^{\circ}$  from temperature scale.
- III. Picric acid-*p*-cresol. Subtract  $10^{\circ}$  from temperature scale.
- IV. Chloroacetic acid-phenol. Add  $20^{\circ}$  to temperature scale.
- V. Picric acid-*o*-toluic acid. Add  $110^{\circ}$  to temperature scale.

A system containing two components of not widely different acidic strength may be predicted not to give oxonium compounds. Thus, in the investigation quoted above, all examples of the two types: weak acid—weak acid and strong acid—strong acid gave on examination uniformly negative results. In the present work, a few examples of the types: weak phenol—weak acid and weak phenol—weak phenol are appended in order to cover the field completely and to illustrate that this rule holds for phenols also.

### I. Systems: Weak Phenol-Strong Acid.

Several investigations have been made on systems of this type by previous workers, but the results have been mainly negative, few addition compounds having been obtained. Maass and McIntosh<sup>1</sup> examined a great number of phenols with hydrobromic and hydrochloric acids, but isolated no compounds except in the case of resorcinol. Gomberg and Cone,<sup>2</sup> on the other hand, obtained addition products of orcinol, phloroglucinol and hydroquinone with HBr, but found no indication of compound formation with resorcinol and other phenols. Kendall and Carpenter<sup>3</sup> isolated a number of oxonium salts of phenols with sulfuric acid.

In the following table the positive results recorded in these researches are summarized: the compositions of the compounds obtained are indicated by condensed formula (A = phenol, B = acid) to economize space.

Systems.	Compounds.	Systems.	Compounds.
Resorcinol-HBr.....	AB <sub>4</sub>	Phenol-H <sub>2</sub> SO <sub>4</sub>	A <sub>2</sub> B
Resorcinol-HCl.....	AB <sub>3</sub> or AB <sub>4</sub>	<i>p</i> -Cresol-H <sub>2</sub> SO <sub>4</sub>	A <sub>2</sub> B; AB <sub>2</sub>
Orcinol-HBr.....	A <sub>2</sub> B	<i>o</i> -Xylenol-H <sub>2</sub> SO <sub>4</sub>	A <sub>2</sub> B; AB
Phloroglucinol-HBr.....	A <sub>2</sub> B	<i>p</i> -Xylenol-H <sub>2</sub> SO <sub>4</sub>	AB; AB <sub>2</sub>
Hydroquinone-HBr.....	?	<i>m</i> -Nitrophenol-H <sub>2</sub> SO <sub>4</sub>	A <sub>2</sub> B
		<i>p</i> -Nitrophenol-H <sub>2</sub> SO <sub>4</sub>	A <sub>2</sub> B

It will be noticed that no single case of compound formation has been previously recorded from a system of the simplest type—monobasic acid and monobasic phenol. The results obtained from such systems in the present investigation are given in the tables below.

1. **Phenol-Trichloroacetic Acid.**—The freezing-point curve of this system is shown in the diagram on page 1313. An equimolecular addition product, C<sub>6</sub>H<sub>5</sub>OH, CCl<sub>3</sub>.COOH, is indicated by the curve; this crystallizes out from a mixture of the two components in the form of beautiful white needles, m. p. 37.6°. The extraordinary flatness of the maximum for this compound on the freezing-point curve shows that it is very considerably dissociated into its constituents on fusion.

### Consideration of Results.

Of the ten phenols examined with trichloroacetic acid, four (phenol and the three cresols) gave equimolecular addition products. The flatness of the maxima on the freezing-point curves indicates that these compounds are very highly dissociated into their components on fusion. In the case of thymol no compound could be isolated, but the form of

the curve leaves no doubt that combination with the acid has occurred.<sup>1</sup> The remaining five systems—the nitrophenols and the naphthols—show no trace of compound formation.

These results, when correlated with the table of acidic strengths on page 1312, are seen to fall in line with the assumptions made regarding the nature of the reaction in the introduction. The more weakly acidic phenols are just capable of forming oxonium salts with trichloroacetic acid and the slight increase in acidity in passing to the nitrophenols and the naphthols is sufficient to inhibit compound formation.

A disparity is evident, however, when the results are compared with those previously obtained for weak acids.<sup>2</sup> These, although of far greater acidic strength than the phenols, give more stable compounds with trichloroacetic acid. The explanation probably lies in the different nature of the group involved in the formation of the oxonium salt. In the case of acids, addition has been assumed to take place on the carbonyl oxygen,<sup>3</sup> whereas with the phenols the only oxygen present is in a hydroxyl group. Thus the two reactions may be distinguished as follows:

It is true that previous investigators<sup>4</sup> have assumed that phenols, in forming addition compounds, first pass over to a tautomeric ketonic form, *i. e.*,

<sup>1</sup> The depression of the freezing point of trichloroacetic acid by thymol is greater than that obtained with similar molecular proportions of the more highly acidic phenols. This slight "dip" (apparent in the curves for the acid in systems 1-5) indicates the presence of a compound in solution (Kendall, *THIS JOURNAL*, 36, 1731-3 (1914)).

<sup>2</sup> Kendall, *THIS JOURNAL*, 36, 1722 (1914).

<sup>3</sup> In conformity with previous workers (compare Hoogewerff and van Dorp, *Rec. trav. chim. Pays-Bas*, 21, 363 (1902)). Some addition, however, must also simultaneously occur upon the hydroxyl oxygen, with the formation of an oxonium

salt of the type:  $\text{R}-\overset{\text{O}}{\underset{\text{H}}{\text{C}}}=\overset{\text{X}}{\text{O}}-\text{H}.$

<sup>4</sup> Gomberg and Cone, *Ann.*, 376, 236 (1911).

(under which assumption addition takes place on the carbonyl group, as in the case of acids) but this is neither a necessary<sup>1</sup> nor, indeed, a satisfactory explanation of the compound formation. Alcohols and ethers, substances with which such a rearrangement is not possible, give well-defined oxonium salts with acids.<sup>2</sup> Here the carbonium structure suggested by Gomberg and Gone for the addition products is altogether excluded, since no double-bonded oxygen is present in the original molecule. The isolation by Maass and McIntosh<sup>3</sup> of addition compounds of resorcinol with acids also conflicts with the conclusions expressed by Gomberg and Cone.<sup>4</sup>

Our present data with regard to oxonium compounds of substances lacking the carbonyl group are, however, insufficient to enable any definite opinion to be expressed as to the mechanism of the reaction. If, as is probable, it forms the first stage in the formation of the phenolic esters or organic acids, then it would seem reasonable to infer that the reaction takes place in successive steps corresponding with those involved in the general process of esterification. The discussion of this subject will be taken up again in a subsequent communication.

## II. Systems: Weak Phenol-Strong Phenol.

The results of previous investigations upon systems of this type are summarized in the following table. It will be seen that a number of simple phenols have already been examined with picric acid, and in some cases addition compounds have been isolated:

Systems.	Compounds.	Observer.
Phenol-picric acid.....	AB	Philip <sup>5</sup>
<i>o</i> -Nitrophenol-picric acid.....	None	Kreemann and Rodinis <sup>6</sup>
<i>m</i> -Nitrophenol-picric acid.....	None	Kreemann and Rodinis
<i>p</i> -Nitrophenol-picric acid.....	None	Kreemann and Rodinis
$\beta$ -Naphthol-picric acid.....	AB	Kuriloff <sup>7</sup>
Catechol-picric acid.....	AB	Philip and Smith <sup>8</sup>
Guaiacol-picric acid.....	AB	Philip and Smith
Resorcinol-picric acid.....	AB	Philip and Smith

The methods employed in the above researches were substantially the same as those of the present paper, the existence and stability of the addition compounds being determined from the freezing-point curve. Consequently the results recorded above are directly available for comparison with those of this investigation, and only those phenols listed on

<sup>1</sup> Kendall and Carpenter, *THIS JOURNAL*, 36, 2511 (1914).

(c) Solid phase,  $C_{10}H_7OH$ .

% $C_6H_2(NO_2)_3OH$ .....	3.2	0
T.....	48.2	49.6

15.  $\alpha$ -Naphthol-Picric Acid.—This system gives an addition product—probably  $C_{10}H_7OH$ ,  $C_6H_2(NO_2)_3OH$ —but the melting point of the compound is so high that mixtures containing more than a small amount of picric acid become very explosive, consequently the curve could not be determined.

### Consideration of Results.

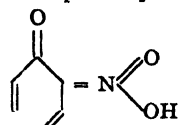

Of the thirteen phenols examined with picric acid in this and previous investigations, ten are found to give addition products, the three nitrophenols alone providing negative results.<sup>1</sup> This is again in accordance with the views advanced in the introductory section regarding the nature of the reaction, since the nitrophenols are the most highly acidic of all those investigated<sup>2</sup> and therefore exhibit the least tendency towards compound formation with a *strong* acid.

When the freezing-point curves of phenols with picric acid are compared with those given with trichloroacetic acid in an earlier section, it is seen that picric acid behaves as the stronger acid of the two. The maxima for the addition compounds with this acid are sharper throughout the whole series of curves in spite of the higher temperatures involved. Picric acid, also, gives addition products with the naphthols, which do not combine at all with trichloroacetic acid. The phenols thus resemble alcohol in being better dissociating media for picric acid than for trichloroacetic, although in aqueous solution the two acids are very nearly equally ionized. In the same way sulfuric acid, as will be evident from the table on page 1314, is a stronger acid than picric in phenol solutions, since it is capable of compound formation even with the nitrophenols. In aqueous solution the order is reversed.

Eight of the ten compounds obtained from systems of the type: weak phenol-picric acid are equimolecular.<sup>3</sup> The reaction for their formation may be expressed, in accordance with the arguments advanced previously,

<sup>1</sup> The system quinol-picric acid gives no compound owing to decomposition of the quinol (Philip and Smith, *J. Chem. Soc.*, 87, 1735 (1905)).

<sup>2</sup> *o*- and *p*-Nitrophenols (also picric acid) may well be stronger acids in the nitronic

forms, , than in the phenol forms. It is instructive to note that *m*-nitrophenol is a much weaker acid than its *o*- and *p*-isomers (see page 1312).

<sup>3</sup> The composition of the  $\alpha$ -naphthol-picric acid compound could not be determined.

by Equation II on page 1317. The compound of *m*-cresol with picric acid is peculiar in containing two molecules of *m*-cresol to one of acid.

### III. Systems: Weak Acid-Strong Phenol.

No previous work has been done upon systems of this class. The examples of this type investigated below gave only negative results, no compounds being isolated. The same is true of two systems of the type: weak acid-weak phenol, which are also recorded in the following tables:

#### 16. Acetic Acid-Picric Acid.—

% $CH_2Cl.COOH$ .....	27.6	17.9	8.6	0
T.....	16.7	21.8	26.6	30.4

## Consideration of Results.

None of the weak acids examined with picric acid in the above tables gave addition compound formation, and the freezing-point curves indicate that no compounds exist in solution. This is an unexpected result, since the same weak acids have been shown to form stable compounds with trichloroacetic acid<sup>1</sup> and with sulfuric acid.<sup>2</sup>

The conclusion must be drawn that the weak organic acids, unlike the phenols, are better dissociating media for trichloroacetic acid than for picric acid. Such differences of behavior, however, as have been noted here and in a preceding section do not deserve much emphasis, since the general results of work in this field indicate that, in cases of such weak combination, quite small variations in atidic strength are sufficient to induce or inhibit the isolation of compounds.

The two systems of the type: weak acid-weak phenol recorded above also gave no addition compounds, as was only to be expected from systems containing two components of not widely different acidic strengths. Similarly Paterno and Ampolla<sup>3</sup> found no compound formation in the systems thymol-acetic acid and thymol-phenol.

## Summary.

The examination of compound formation in two-component systems of the type: strong organic acid-weak organic acid has been completed by including phenols in the investigation. Systems of the general type: phenol-acid have been studied in which the acidic strengths of both components have been varied as widely as possible.

In accordance with the results of previous papers, it has been found that addition compounds are obtained only when the acidic strengths of the two components are very widely separated. Thus weak phenols give oxonium salts with a strong acid or a strongly acidic phenol (trichloroacetic acid or picric acid). A number of such compounds have been

<sup>1</sup> Kendall, *THIS JOURNAL*, 36, 1722 (1914).

<sup>2</sup> Kendall and Carpenter, *Ibid.*, 36, 2498 (1914).

<sup>3</sup> Paterno and Ampolla, *Gazz.*, 27, 481 (1897).

isolated and described. Systems containing components of not so widely divergent ædic strengths give no compound formation.

The reaction is assumed to be similar in its nature to those studied in previous papers, *i. e.*, the compounds are regarded as true oxonium salts. The equation may be written as follows:

This reaction probably represents the first stage in the formation of phenolic esters of organic acids. The further study of the mechanism of the esterification process will be the subject of a subsequent paper.

## VI. FURTHER EVIDENCE FOR THE ELECTRONIC FORMULA OF BENZENE AND THE SUBSTITUTION RULE.<sup>1</sup>

By HARRY SHIPLEY FRY.

Received April 13, 1916.

In previous papers of this series<sup>2</sup> numerous facts have been presented and interpreted by means of the electronic formula of benzene (abbreviated formula, Fig. 1). A substitution rule was indicated maintaining that

Fig. 1.

when substituents are of the same sign or polarity they will occupy positions which are meta to each other, but if two substituents are of opposite sign or polarity they will occupy either ortho or para positions to each other. This follows from the fact that the electronic formula of benzene is the only formula presenting conjointly a structural basis and an electronic interpretation of the relations between the ortho and para positions and substituents in contradistinction to the meta positions and substituents.

The purpose of the present paper is to present briefly additional experimental facts which further substantiate the electronic formula of benzene and the substitution rule. The facts here offered seem particularly significant since they involve polysubstituted derivatives of benzene.

Phenol, when directly nitrated, yields ortho- and para-nitrophenols. Further nitration yields the two isomeric 1,2,4- and 1,2,6-dinitrophenols.

<sup>1</sup> This and the two following papers constitute Parts VI, VII, and VIII of the series, "Interpretations of Some Stereochemical Problems in Terms of the Electronic Conception of Positive and Negative Valences." Parts VI and VIII were read before the Cincinnati Section of the American Chemical Society, May 12, 1915.

<sup>2</sup> Fry, *THIS JOURNAL*, 36, 248, 262, 1035 (1914); *Ibid.*, 37, 855, 863, 883, 2368 (1915); see also Fry, *Z. physik. Chem.*, 76, 385, 398, 591 (1911); *Ibid.*, 80, 29 (1912); *Ibid.*, 82, 665 (1913); *Ibid.*, 90, 458 (1915).

Finally, nitration of either of these products gives the symmetrical trinitro derivative, picric acid. These reactions are summarized in the following electronic equation:<sup>1</sup>

In trinitrophenol each of the nitro groups is positive but the electronic formula indicates that in tetranitrophenol a fourth nitro group in position 3 or 5 would be negative. Now if some nitro groups are positive and others are negative there should be some marked difference in their behavior toward certain reagents. These conclusions are substantiated by the fact that "the nitro group in nitrobenzene is extremely stable compared with the fourth nitro group in tetranitrophenol, which water will remove in the form of nitrous acid."<sup>2</sup> These facts are in perfect agreement with the electronic formula of tetranitrophenol, the hydrolysis of which yields nitrous acid ( $\text{H}.\text{NO}_2$  or  $\text{H}.\text{ONO}$ )<sup>3</sup> according to the electronic equation

Since direct nitration with nitric acid results in the substitution of positive nitro groups and since in tetranitrophenol the negative nitro group may occupy either of the equivalent positions 3 or 5, with negative hydroxyl in position 1, it follows that substituents in positions 1, 3, and 5 are negative while those in positions 2, 4, and 6 are positive. This is a confirmation of the electronic formula of benzene and the substitution rule stated above.

In previous papers it has been shown that hydrogen-,<sup>4</sup> halogen-, hydroxyl-sulfonic,<sup>5</sup> and carboxyl-radicals<sup>6</sup> may function either positively or negatively, depending principally upon the relative positions they may occupy in the benzene nucleus. Now with reference to the existence of positive

<sup>1</sup> For detailed description of the mechanism of substitution, see Fry, *THIS JOURNAL*, 37, 875 (1915).

<sup>2</sup> Cohen, "Organic Chemistry," Vol. II, p. 90.

<sup>3</sup> For tautomeric and electronic formulas of nitrous acid see Fry, *THIS JOURNAL*, 37, 875 (1915) and *Z. physik. Chem.*, 90, 464 (1915).

<sup>4</sup> Fry, *THIS JOURNAL*, 36, 262 (1914).

<sup>5</sup> *Ibid.*, 37, 864 (1915).

<sup>6</sup> *Ibid.*, 36, 256 (1914).

in the 2,4,6-compound the nitro groups in positions 4 and 6 are also regarded as positive since they are not replaced by  $\text{NH}_2$ . They occupy positions ortho- and para-, respectively, to the negative nitro group of position 3. All of these facts and conclusions are embodied in and interpreted by the following electronic formulas and equations:

In all benzene formulas positions 2 and 6 are equivalent as are also positions 3 and 5. Accordingly, the 2,3,4- and 3,4,6-trinitrodimethylanilines (and their products of interaction with ammonia) coincidentally show that when the substituents in positions 1, 3, and 5 are negative, the substituents in positions 2, 4, and 6 are positive. This also constitutes a further substantiation both of the electronic formula of benzene and the substitution rule.

Additional evidence leading to the above conclusions might be described in detail but brief mention may suffice. Michele Giua<sup>1</sup> and A. Contardi<sup>2</sup> have described a number of polynitro derivatives of benzene which suffer replacement of a nitro group by OH, O(CH<sub>3</sub>), NH<sub>2</sub> and NH(CH<sub>3</sub>) with the liberation of nitrites. In some instances hydrolysis with water yields nitrous acid anhydride. In these various instances two nitro groups are adjacent, *i. e.*, occupy positions ortho- to each other, and only one of them suffers replacement. Giua maintains that this behavior substantiates the rule on the reactivity of the nitro groups in the benzene ring proposed by Körner and Laubenheimer who attribute the facility of reaction of the one nitro group to the adjacency of the two nitro groups and the consequent "loosening" action of one group upon the other. This interpretation is not only vague but it fails to take into account the highly significant facts that the nitro group is replaced by a substituent of *negative polarity* and that the group thus replaced is liberated as a *nitrite* in which the *nitro radical is also negative*. The electronic conception of positive and

<sup>1</sup> *Atti accad. Linc-i*, 23, 484 (1914); *Gazz. chim. ital.*, 45, 339, 352 (1915).

<sup>2</sup> *Ibid.*, 23, 464 (1914).

negative valences and the existence of positive and negative nitro groups affords a more satisfactory interpretation, since all of the facts noted are indicated and correlated by the electronic formula of benzene and the substitution rule. Conversely, the facts verify the electronic formula of benzene and the substitution rule.

## VII. THE ACTION OF SODIUM METHYLATE UPON THE PRODUCTS OF NITRATION OF ORTHO-, PARA- AND META-CHLOROTOLUENES.

By HARRY SHIPLEY FRY.

Received April 13, 1916.

Part IV<sup>1</sup> of this series considered in detail the simultaneous formation of *o*-, *p*-, and *m*-substituted derivatives of benzene from the standpoint of the electronic tautomerism of benzene derivatives.<sup>2</sup> The present paper (VII) is a continuation of Part IV and embodies the results of a quantitative study of the action of sodium methylate solutions of various concentrations upon the products of nitration of *o*-, *p*-, and *m*-chlorotoluenes. The results of these experiments, in addition to the facts given in Part IV, are offered as further evidence for the electronic tautomerism<sup>3</sup> of certain substituted derivatives of benzene.

In order to follow the experimental part of this work it will be necessary to indicate briefly, from the standpoint of the conception of electronic tautomerism, the electronic equations for the nitrations of *o*-, *p*-, and *m*-chlorotoluenes according to the following Schemes 1, 2, and 3, respectively.

**Scheme 1.**—The nitration of *o*-chlorotoluene.

<sup>1</sup> Fry, *THIS JOURNAL*, 37, 863 (1915).

<sup>2</sup> Fry, *Z. physik. Chem.*, 76, 390 (1911); *THIS JOURNAL*, 37, 864 (1915).

<sup>3</sup> For a detailed account of the mechanism of the electronic tautomerism of benzene derivatives see Fry, *THIS JOURNAL*, 37, 873 (1915).

**Scheme 2.**—The nitration of *p*-chlorotoluene.**Scheme 3.**—The nitration of *m*-chlorotoluene.

The above schemes were the bases of the interpretations of the nitration reactions of Wibaut,<sup>1</sup> Holleman<sup>2</sup> and Wibaut,<sup>3</sup> respectively, who determined the percentage yields of the several isomers of each nitration by physical methods—processes of fractional crystallization and comparisons of curves of fusion of mixtures of unknown composition with those of known composition.

In each of these schemes it will be observed that the nitration products (A', A'', etc.) of the electromer A embody negative chlorine while those (B', B'', etc.) of electromer B embody positive chlorine. Now, if it be possible to show by quantitative chemical methods that the yields of the isomers (chloronitrotoluenes) which contain negative chlorine are commensurate with the yields of the same isomers ascertained by Holleman and Wibaut by physical methods, then the conception of the electronic tautomerism of the chlorotoluenes as indicated in Schemes 1, 2, and 3, is, in a measure, substantiated.

The chemical method for the determination of the yields of the isomers containing negative chlorine depends, first, upon the completeness of

<sup>1</sup> *Recueil*, 32, 244 (1913).

<sup>2</sup> *Ibid.*, 28, 408 (1909).

<sup>3</sup> *Ibid.*, 32, 244 (1913).

their interaction with sodium methylate and, second, the noninteraction of the isomers containing positive chlorine. In order to test the applicability of these two points, the action of sodium methylate in methyl alcohol solution upon *o*-, *p*-, and *m*-chloronitrobenzenes was investigated. These isomers were chosen because it is commonly recorded that the *o*- and *p*-isomers exchange their halogen atom for OH, O(CH<sub>3</sub>) or NH<sub>2</sub>, while the *m*-isomer is nonreactive.

An interpretation of these reactions has been given<sup>1</sup> from the standpoint of the electronic formula of benzene and the substitution rule. The abbreviated electronic formulas of the chloronitrobenzenes are as follows:

Only those isomers containing negative halogen (*o*- and *p*-) should interact with sodium methylate, thus,

and the *m*-isomer, containing positive chlorine, should be nonreactive under the same conditions.

The extent of the replacement of negative chlorine can be found by determining the quantity of sodium chloride liberated. After repeated experiments, designed to secure the conditions noted, the following method was found to yield theoretical results: About 0.2 g. of the chloronitrobenzene was dissolved in 15 cc. of a normal solution of sodium methylate in absolute methyl alcohol. The solution was heated in a sealed glass tube for 5 hours at 100°. The contents of the tubes were then diluted to a volume of 200 cc., acidified with nitric acid, boiled to expel the methyl alcohol, cooled, and filtered. The quantity of sodium chloride in the respective filtrates was determined by titration with standard solution of silver nitrate. The following results were obtained:

Substance.	(Grams.)	No. cc. 0.9957 N AgNO <sub>3</sub> solution.	% negative Cl. Found.	% negative Cl. Theor.
$\text{O-Cl.C}_6\text{H}_4\text{.NO}_2$ .....	0.2005	12.81	22.56	22.51
$\text{P-Cl.C}_6\text{H}_4\text{.NO}_2$ .....	0.2007	12.78	22.48	22.51
$\text{m-Cl.C}_6\text{H}_4\text{.NO}_2$ .....	0.1992	00.00	00.00	00.00

These results show that isomers containing negative chlorine may be estimated quantitatively, provided conditions are secured for their complete interaction with sodium methylate, while under the same conditions the isomer containing positive chlorine is nonreactive.

<sup>1</sup> Fry, Z. *physik. Chem.*, 76, 395 (1911); THIS JOURNAL, 36, 253 (1914).

The chief problem of the present investigation was to secure conditions under which the negative halogen atoms of the nitration products of *o*-, *p*-, and *m*-chlorotoluenes would completely interact with sodium methylate and thus afford a chemical method for determining the percentage yields of the isomers of chloronitrotoluene which contain negative chlorine. A comparison of the chemically determined and the physically determined yields could then be made. With this end in view, *o*-, *p*-, and *m*-chlorotoluenes were each separately nitrated (at 0°) according to the specific directions given by Wibaut, Holleman and Wibaut, respectively.<sup>1</sup> The methods were originally designed to yield only mononitro substitution products. The respective products of nitration of each of the chlorotoluenes, which consisted of mixtures of the different isomers (nitrochlorotoluenes), as indicated in the preceding Schemes 1, 2, and 3, were treated with sodium methylate solutions of varying concentrations—0.5 *N*, *N*, 2 *N* and 3 *N*. Samples, 0.2 to 0.4 g., of the nitration products were heated, each with 15 cc. of the sodium methylate solution in sealed tubes, for 10 hours at 100°. The contents of the tubes were then analyzed, as previously described, for the negative chlorine, liberated as  $\text{Na}^+\text{Cl}^-$ , precipitated and weighed as silver chloride. The percentage yield of the combined isomers containing negative chlorine was calculated from the ratio  $\text{Ag}^+\text{Cl}^- : \text{Cl}^-\text{NO}_2\text{CH}_3\text{C}_6\text{H}_5$ . The results of these experiments are recorded in three sections (I, II and III) to correspond with Schemes 1, 2, and 3 for the nitration of *o*-, *p*-, and *m*-chlorotoluenes, respectively. All reactions were conducted in duplicate.

TABLE I.

I. Action of Sodium Methylate upon the Isomers Derived from *o*-Chlorotoluene. (See Scheme 1.)

Mixture of isomers (gram).	Normality NaOCH <sub>3</sub> .	AgCl (gram).	% yield of isomers A' + A'', 1,2,6- and 1,2,4-Cl, CH <sub>3</sub> , NO <sub>2</sub> , C <sub>6</sub> H <sub>5</sub> .			Average.
			1,2,6-	1,2,4-	Average	
0.2625	0.5 <i>N</i>	0.1163		53.01		
0.2434	0.5 <i>N</i>	0.1084		53.29		53.15
0.2835	<i>N</i>	0.1388		58.58		
0.2938	<i>N</i>	0.1446		58.89		58.73
0.3283	2 <i>N</i>	0.1362		49.64		
0.2994	2 <i>N</i>	0.1254		50.12		49.83
0.2772	3 <i>N</i>	0.0884		38.16		
0.2940	3 <i>N</i>	0.0941		39.30		38.23

These results indicate that the extent of the reaction with sodium methylate is greatest in the normal solution. A 58.73% yield of the combined isomers containing negative chlorine was obtained. The yields of these isomers determined by the physical methods of Wibaut<sup>1</sup> totals 62.20%.

<sup>1</sup> *Loc. cit.*

The yields obtained by the two methods, while not identical, approximate closely. Variations will be considered later.

TABLE II.

II. Action of Sodium Methylate upon the Isomers Derived from *p*-Chlorotoluene. (See Scheme 2.)

Mixture of isomers (gram).	Normality NaOCH <sub>3</sub>	AgCl (gram).	% yield of isomer A', 1,2,4-Cl, NO <sub>2</sub> , CH <sub>3</sub> , C <sub>6</sub> H <sub>5</sub> .	Average.
			— + +	
0.2707	0.5 <i>N</i>	0.0799	35.33	
0.2868	0.5 <i>N</i>	0.0842	35.13	35.23
0.3068	<i>N</i>	0.0946	36.89	
0.2608	<i>N</i>	0.0773	35.47	36.18
0.2854	2 <i>N</i>	0.0750	31.44	
0.3068	2 <i>N</i>	0.0780	30.42	30.93
0.3297	3 <i>N</i>	0.0814	29.54	
0.3037	3 <i>N</i>	0.0769	30.30	29.92

Here also the extent of the reaction with sodium methylate was greatest in the normal solution, which indicated a yield of 36.18% of the isomer containing negative chlorine. The yield of the same isomer determined by Holleman (fusion curve method) was 42.00%.

TABLE III.

III. Action of Sodium Methylate upon the Isomers Derived from *m*-Chlorotoluene. (See Scheme 3.)

Mixture of isomers (gram).	Normality NaOCH <sub>3</sub>	AgCl (gram).	% yield of isomers A' + A'' + A''', 1,3,6- + 1,3,4- + 1,3,2-CH <sub>3</sub> , Cl, NO <sub>2</sub> , C <sub>6</sub> H <sub>5</sub> .	Average.
			— + +	
0.2257	0.5 <i>N</i>	0.1652	87.59	
0.2510	0.5 <i>N</i>	0.1843	87.86	87.77
0.2672	<i>N</i>	0.1987	88.99	
0.2520	<i>N</i>	0.1853	87.99	88.49
0.2670	2 <i>N</i>	0.1898	85.06	
0.3212	2 <i>N</i>	0.2308	85.98	85.52
0.2809	3 <i>N</i>	0.1923	81.92	
0.2808	3 <i>N</i>	0.1888	80.46	81.19

Again the extent of the reaction was greatest in the normal solution indicating a yield of 88.49% of the three isomers containing negative chlorine. Wibaut (fractional crystallization and fusion curve methods) obtained a 100% yield of these isomers.

The yields of the isomers containing negative chlorine determined by physical methods and the maximum yields of the same isomers determined by chemical methods are summarized in the following table:

TABLE IV.

Scheme.	Isomers.	Physical.	Chemical.	% Ratio.
1.....	(A' + A'')	62.20 (Wibaut)	58.73 (Fry)	94.42
2.....	(A')	42.00 (Holleman)	36.18 (Fry)	86.14
3.....	(A' + A'' + A''')	100.00 (Wibaut)	88.49 (Fry)	88.49

The extreme care with which Holleman and Wibaut conducted their physical determinations leads one to accept their results as practically final. Accordingly, in the last column above, the chemically determined yields are recorded as percentages of the physically determined yields. If each of the values in the last column was 100% then it might be assumed without question that the conception of the electronic tautomerism of the *o*-, *p*-, and *m*-chlorotoluenes given in Schemes 1, 2, and 3, respectively, is completely substantiated. Without making this assumption or claim it may, nevertheless, be maintained that in so far as the values in the last column do approach the theoretical, so far do they substantiate the electronic tautomerism of the chlorotoluenes. Moreover, it may be said that the electronic tautomerism of *o*-, *p*-, and *m*-chlorotoluenes is the only hypothesis that has accounted for the replaceability of certain halogen atoms in some of the isomeric nitrochlorotoluenes and the nonreplaceability of certain halogen atoms in others. The data presented in this paper substantiate the hypothesis.

The fact that the chemically determined quantities of the isomers containing negative chlorine were less than the quantities determined by physical methods may have been due to two causes. First, the interaction with sodium methylate of one or more of these isomers in the mixtures may have been incomplete. This is not likely, since the results of the experiments with the analogous chloronitrobenzenes gave results in perfect agreement with the theory. Furthermore, a survey of the quantitative data given in connection with Schemes 1, 2, and 3 shows a maximum replacement in every reaction in which the uninormal solutions of sodium methylate were used. Concentrations below or above normal gave lower yields.

In the second place, the low yields of the isomers containing negative chlorine may be due to the fact that the relative quantities of the isomers obtained on nitration of the chlorotoluenes in Holleman's laboratories may not have been identical with the relative quantities of the same isomers obtained in this laboratory, even though the original directions given by Holleman and Wibaut were carried out precisely. The variations are most likely due to lack of standardization in certain details of manipulation, such as the rate of the addition of the nitric acid, methods of stirring, cooling, etc. While the temperature variations were kept within the prescribed limits, primarily to avoid the formation of polynitro derivatives, it is quite likely that the local temperature effects in the reaction mixture may have altered the relative quantities of the isomers formed. In fact, when nitrations were conducted separately, but under identical conditions, variations in the fusion points of the resulting mixtures were noted. This signifies corresponding variations in the relative quantities of the isomers in these mixtures.

In conclusion, the variations between the chemically and the physically determined yields are not sufficient to invalidate the principle of the electronic tautomerism of the chlorotoluenes. The conception affords a consistent interpretation of the observed facts and is substantiated in a great measure by the quantitative data offered in this paper. In the following paper (Part VIII) the conception of electronic tautomerism is developed further and confirmed more completely.

### VIII. FURTHER EVIDENCE FOR THE ELECTRONIC TAUTOMERISM OF BENZENE DERIVATIVES.<sup>1</sup>

By HARRY SHIPLEY FRY.

Received April 13, 1916.

The purpose of the present paper is to consider certain experimental facts, the interpretation of which fully warrants the assumption of the existence of electromers in dynamic equilibrium, *i. e.*, electronic tautomerism. Quantitative data will also be presented which conclusively confirm the principle of electronic tautomerism. A few underlying principles should be recalled.

Hydrolysis reactions commonly constitute an experimental method<sup>2</sup> for designating the polarity of the radicals of a compound under the particular conditions of hydrolysis. The following general scheme embodies the theoretical and the actual possibilities presented by hydrolysis reactions:

If the compound in question, XY, on hydrolysis yields only H.Y and HO.X, then XY is qualified by the electronic formula  $\overset{+}{X}-\overset{-}{Y}$ , or  $\overset{+}{X}.Y$ . If, on the other hand, conditions are such that hydrolysis yields only H.X and HO.Y, then XY is qualified by the formula  $\overset{-}{X}.Y$ . In some reactions the four possible products are obtained and, accordingly, the compound XY presents an illustration of electronic tautomerism, *i. e.*, the existence of both electromers  $\overset{+}{X}.Y \rightleftharpoons \overset{-}{X}.Y$  in dynamic equilibrium. A number of instances<sup>3</sup> has been recorded, in which reactions proceed

<sup>1</sup> Read before the Cincinnati Section of the American Chemical Society, May 12, 1915.

<sup>2</sup> Fry, *Z. physik. Chem.*, 76, 395 (1911); W. A. Noyes, *THIS JOURNAL*, 23, 460 (1901) and Stieglitz, *THIS JOURNAL*, 23, 796 (1901) were the first to employ hydrolysis reactions as a means of indicating the polarities of the radicals of substances.

<sup>3</sup> Fry, *THIS JOURNAL*, 37, 864 (1915); L. W. Jones, *Am. Chem. J.*, 50, 414 (1913).

according to the above and analogous schemes, and therefore substantiate the existence of electromers and electronic tautomerism. Particularly significant, in this connection, are the nitrations of the mixed dihalogen benzenes and the subsequent hydrolyses of their nitration products with sodium methylate. Some remarkable consequences may now be predicted if we consider the mixed dihalogen benzenes from the standpoint of the electronic formula of benzene and the principle of electronic tautomerism.

When two substituents occupy positions either ortho or para to each other they are of opposite polarity. Hence in the electronic formula for a *p*-dihalogen benzene in which the halogen atoms X and Y are different chemically, it follows that if X is negative, Y is positive; or, if X is positive, Y is negative. Now, in the nitration of a *p*-disubstituted derivative of benzene only two mononitro substitution products are possible, and, from the standpoint of the principle of electronic tautomerism as applied to a *p*-dihalogen benzene, the nitration reaction should conform to the following general scheme:

If the principles underlying this general<sup>a</sup> scheme are correct, then certain definite consequences follow which should lend themselves to verification by experiment. What are some of these consequences? If the electromers of  $\text{C}_6\text{H}_4\text{XY}$  (designated as A and B) are in tautomeric equilibrium and if each electromer interacts with nitric acid, the respective isomers, A' and B', should be formed. Note particularly that in the isomer A', X is negative and Y is positive, while in isomer B', X is positive and Y is negative. In view of the facts presented in the preceding paper, notably the action of sodium methylate upon *o*-, *p*-, and *m*-chloronitrobenzenes, it follows that isomer A' on interaction with sodium methylate ( $\text{Na}\cdot\text{OCH}_3$ ) should exchange X for  $\text{OCH}_3$  and liberate  $\text{Na}\cdot\text{X}$  according to Equation 1.

On the other hand, isomer B' should exchange  $\text{Y}^-$  for  $\text{OCH}_3^-$  and liberate  $\text{Na}\cdot\text{Y}$  according to Equation 2:

Furthermore, if electromers A and B are in tautomeric equilibrium and nitration yields a mixture of isomers A' and B' then the action of sodium methylate upon this mixture should yield not only the oxymethyl derivatives, A'' and B'', (Equations 1 and 2, respectively) but also a mixture of the sodium halides,  $\overset{+}{\text{Na}}.\overset{-}{\text{X}}$  and  $\overset{+}{\text{Na}}.\overset{-}{\text{Y}}$ . An experimental verification of these predictions would lead to a very definite conclusion, namely, that the *para* mixed dihalogen compound,  $\text{C}_6\text{H}_4\text{XY}$ , affords an example of electronic tautomerism. Otherwise it would be difficult, if not impossible, to account for the simultaneous formation of the halides,  $\overset{+}{\text{Na}}.\overset{-}{\text{X}}$  and  $\overset{+}{\text{Na}}.\overset{-}{\text{Y}}$ , when sodium methylate interacts with the products of nitration of the mixed dihalogen benzene.

Experimental facts will now be considered which are completely in agreement with the principles and general reactions just postulated. Holleman<sup>1</sup> and Heineken have made a thorough study of the nitration (at 0°) of various mixed dihalogen benzenes. For the present, attention will be confined to the nitration of *p*-chlorobromobenzene, which gave a mixture of the isomers 1,2,4- and 1,3,4-chloronitrobromobenzenes. In developing a quantitative chemical method for determining the yields of these isomers in the nitration mixture, Holleman found that the 1,2,4-isomer heated with 0.35 *N* sodium methylate solution in a sealed tube for five hours at 80° gave practically complete displacement of chlorine as sodium chloride while the bromine remained intact. The reaction proceeded quantitatively (98.40%) according to Equation 3.

Note that this reaction is perfectly analogous to Equation 1, given above, in which  $\overset{-}{\text{X}}$  may now be  $\overset{-}{\text{Cl}}$ , and  $\overset{+}{\text{Y}}$  may be Br. The liberated sodium halide is  $\overset{+}{\text{Na}}.\overset{-}{\text{Cl}}$ . In other words, the 1,2,4-isomer (A') has the electronic formula

<sup>1</sup> *Recueil*, 34, 204 (1915).

otherwise the liberation of chlorine as Na.Cl is inexplicable.

On the other hand, the 1,3,4-isomer on interaction with sodium methylate (under identical conditions) suffered *practically complete displacement of bromine as sodium bromide while the chlorine atom remained intact*. The reaction proceeded quantitatively (98.00%) according to Equation 4.

Note that this reaction is perfectly analogous to Equation 2 above, in which  $\overset{+}{\text{X}}$  may now be  $\overset{+}{\text{Cl}}$ , and  $\overset{-}{\text{Y}}$  may be  $\overset{-}{\text{Br}}$ . The liberated sodium halide is Na.Br. In other words, the 1,3,4-isomer (B') has the electronic formula

otherwise the liberation of bromine as Na.Br is inexplicable.

The quantitative interaction of 1,2,4- and 1,3,4-chloronitrobromobenzene with sodium methylate enabled Holleman to determine the relative quantities of these isomers obtained on nitrating *p*-chlorobromobenzene. The sodium chloride and sodium bromide liberated were precipitated as silver chloride and bromide. An analysis of the mixed precipitates gave the percentage yields of the isomers calculated upon the ratios AgCl: 1,2,4-isomer, and AgBr: 1,3,4-isomer. These calculations were based upon Equations 3 and 4 which are perfectly analogous to the preceding electronic Equations 1 and 2, respectively. The yields of the isomers were 45.20% and 54.80%, respectively. The complete correlation of all of these reactions with the electronic formulas and the principle of electronic tautomerism is embodied in the following scheme:

Now a survey of the above scheme shows that those molecules of 1,4-chlorobromobenzene which interact with nitric acid to give the 1,2,4-isomer, which in turn exchanges its *chlorine* atom for  $\text{OCH}_3$  and yields *sodium chloride*, cannot be identical with the molecules of 1,4-chlorobromobenzene which interact with nitric acid to give the 1,3,4-isomer, which in turn exchanges its *bromine* atom for  $\text{OCH}_3$  and yields *sodium bromide*. In other words, the 1,2,4-isomer (A'), containing  $\text{Cl}^-$  and  $\text{Br}^+$ , must be derived from molecules of 1,4-chlorobromobenzene which also contain  $\text{Cl}^-$  and  $\text{Br}^+$ , i. e., electromer A; and the 1,3,4-isomer (B'), containing  $\text{Cl}^+$  and  $\text{Br}^-$ , must be derived from molecules of 1,4-chlorobromobenzene which also contain  $\text{Cl}^+$  and  $\text{Br}^-$ , i. e., electromer B. Thus the existence of two types of molecules of 1,4-chlorobromobenzene, namely electromers A and B, is conclusively indicated. Their simultaneous interaction with nitric acid indicates tautomeric equilibrium. The relative yields of the isomers A' and B' are functions of the speeds of interaction of nitric acid with the respective electromers A and B, and, as shown in a previous paper,<sup>1</sup> the speeds of interaction are intimately related to the concentrations of the respective electromers in the reaction mixture.

It will not be necessary to extend this paper by giving similarly detailed descriptions of the nitrations of other mixed dihalogen benzenes,<sup>2</sup> since each example conforms perfectly to the schemes and principles presented in this and preceding papers. In conclusion, it is maintained

<sup>1</sup> See Parts III and IV of this series (Fry, *Loc. cit.*).

<sup>2</sup> *p*-Fluorochloro-, *p*-fluorobromo-, *p*-chloroiodo-, *o*-chlorobromo-, *o*-chloroiodo-, and *o*-bromoiodo benzene.

that each of these cases further substantiates the principle of electronic tautomerism or the existence of electromers in dynamic equilibrium.<sup>1</sup>

## 4-NITRO-5-METHYL-2-SULFOBENZOIC ACID AND SOME OF ITS DERIVATIVES.

BY WILLIAM J. KARSLAKE AND PERRY A. BOND.

Received March 29, 1916.

In an earlier paper<sup>2</sup> we have shown that when 6-nitro-1,3-dimethylbenzene-4-sulfonic acid is oxidized by potassium permanganate in very dilute potassium hydroxide solution, three main products are formed, to wit, 6-nitro-3-methyl-4-sulFOBenzoic acid, 4-nitro-5-methyl-2-sulFOBenzoic acid and 6-nitro-4-sulfoisophthalic acid. Sometime later, Karslake and Huston<sup>3</sup> made derivatives of 6-nitro-3-methyl-4-sulFOBenzoic acid. The present work was undertaken to complete our knowledge of the second of these three acids.

In our previous work, 4-nitro-5-methyl-2-sulFOBenzoic acid was obtained in the form of the neutral potassium salt as the first crop of crystals from the oxidized nitro-xylene sulfonic acid. Analyses of this salt were persistently low in potassium. Since then it has been found that this first crop of crystals is usually contaminated with unoxidized 6-nitro-1,3-dimethylbenzene-4-sulfonic acid in the form of the potassium salt. The separation was accomplished finally by systematic fractional crystallization, the crystals being filtered off first from the fairly concentrated solution at 50°, and then from the cold, somewhat diluted filtrate after stand-

<sup>1</sup> Any objection to the use of the conception of electronic tautomerism on the grounds that electronic isomers (electromers) have not as yet been isolated is unwarranted because the conception of tautomerism, both in its historical and practical aspects, neither involves nor demands the immediate possibility of the isolation of the tautomers. In 1885, Laar (*Ber.*, 18, 648 (1885)), in a paper "Ueber die Möglichkeit mehrerer Strukturformeln für dieselbe chemisch Verbindung," defined tautomerism as the phenomenon of one substance doing duty for two structural isomers, *but the isolation of dynamic isomers or desmotropes was not effected until 1893*, the earliest examples being acetyldibenzoylmethane, tribenzoylmethane, and mesityloxide-oxalic ester described by Claisen (*Ann.*, 277, 183 (1893); 291, 25 (1896)). Strictly speaking, the term *tautomeric* is now applied to substances in which *only the equilibrium mixture of the structural isomers is known*; the term *desmotropic* is employed in cases where the isomers have been shown to be capable of independent existence. (Clarke, "Organic Chemistry," p. 251) The existence of electromers in dynamic equilibrium has been conclusively indicated. Their isolation as *electronic desmotropes* has not as yet been effected. Further discussion of this phase of the subject is reserved for future papers.

<sup>2</sup> THIS JOURNAL, 31, 405 (1909).

<sup>3</sup> *Ibid.*, 31, 1057 (1909).

ing several hours. The products thus obtained were recrystallized with due attention to temperature and concentration, until a complete separation was effected. About one hundred separate crystallizations were made in purifying the 235 grams of potassium salt used as a basis for this research. The influence of the impurity has very definite effects, and its removal was a necessity, as will be seen especially in the preparation of the acid chlorides. Analyses of the purified potassium salt, while slightly low, are much better than before.

Calc. for  $C_8H_5O_7NSK_2$ : K, 23.21. Found: K, 22.95, 23.01.

The **Neutral Lead Salt**,  $C_8H_5O_7NSPb + 3H_2O$ , was prepared by adding slightly more than the calculated amount of lead nitrate to the water solution of the potassium salt. It crystallizes quickly from moderately concentrated solution in fine crystals, which in some cases form leaf-like groups. Lead was determined by direct ignition in the crucible as the sulfate.

Calc. for Pb, 39.8;  $H_2O$ , 10.38. Found: Pb, 39.45;  $H_2O$ , 10.00.

The **Acid Potassium Salt**,  $C_8H_5O_7NSK + H_2O$ , was prepared in two ways: either by precipitating the silver from the silver potassium salt by dilute hydrochloric acid, evaporating and crystallizing; or by recrystallizing the neutral potassium salt from very concentrated hydrochloric acid. In the latter case, unless the hydrochloric acid is strong in the solution, the neutral potassium salt crystallizes out again, probably on account of its lesser solubility in water. The acid potassium salt once formed, however, can be recrystallized from water without decomposition. It comes out of the solution in beautiful, fine needles containing one molecule of water of crystallization.

Calc. for K, 12.33; acid hydrogen, 0.315;  $H_2O$ , 5.67.

Found: K, 11.81, 11.92; acid hydrogen, 0.317;  $H_2O$ , 5.74.

The **Free Acid**,  $C_8H_5O_7NS + 3H_2O$ , was prepared from the pure neutral silver salt by adding just a trifle more than the calculated amount of 0.1 *N* hydrochloric acid to the water solution of the salt, boiling, filtering, and evaporating to a small volume. The acid crystallized from water in plate-like needles strongly rosetted and easily broken. It had only a slight yellowish tint. It was insoluble in ether, ligroin, and carbon tetrachloride. It was soluble in acetone, ethyl acetate, or glacial acetic acid. Its melting point when it was crystallized from acetone or alcohol was  $94^\circ$ . The acid was titrated with sodium hydroxide, using phenolphthalein as the indicator.

Calc. for N, 4.44; acid hydrogen, 0.635;  $H_2O$ , 17.14.

Found: N, 4.45; acid hydrogen, 0.626;  $H_2O$ , 17.22.

**The Acid Chlorides.**—It was formerly stated<sup>1</sup> that the treatment of the

<sup>1</sup> *Loc. cit.* (Karslake and Bond).

potassium salt of the 4-nitro-5-methyl-2-sulfobenzoic acid with phosphorus pentachloride in a flask with reflux condenser at boiling temperature produced an oily substance which solidified with difficulty, but on being dissolved in carbon tetrachloride, dried, and partly evaporated, gave two products, one melting at  $133^{\circ}$ , the other an oily substance for which a melting point of  $93^{\circ}$  was suggested. It had been the experience of others<sup>1</sup> that the low-melting and high-melting chlorides crystallized in a constant melting mixture which had a lower melting point than that of the low-melting chloride. The two were separated in these cases by distilling in a vacuum.

The formerly observed melting point for the high melting chloride is approximately correct, the new value adopted being  $134^{\circ}$ , but now it has been definitely shown that the low melting point acid chloride melts at  $83^{\circ}$ , and is not involved as the prime cause of the oily mixture. In this case, as distinguished from the experience of others, no oil was produced when pure initial potassium salt was used, the two chlorides crystallizing out in absolutely distinct crystalline form. They were separated by fractional crystallization, and the symmetrical, high-melting chloride showed a tendency toward the formation of supersaturated solutions in carbon tetrachloride, the solvent used for the purification. The oily mass formerly found was, however, reproduced by mixing with the low-melting acid chloride, a portion of the acid chloride of the unoxidized nitro-xylene sulfonic acid. Its source in that work was evidently the impurity mentioned at the beginning of this paper.

**Symmetrical Acid Chloride,**  $\text{NO}_2.\overset{4}{\text{CH}_3}.\overset{5}{\text{C}_6\text{H}_2}.\overset{2}{\text{SO}_2}\overset{1}{\text{Cl.COCl}}$ .—The symmetrical acid chloride was formed in the largest amounts when the potassium salt of the acid was treated with phosphorus pentachloride in an open dish at the temperature of the steam bath, the ratio of the symmetrical to the unsymmetrical acid chloride thus formed being about three to five, and the total yield reaching 75% of the theoretical.

When the heating had caused complete liquefaction of the mass in the open dish, it was removed from the steam bath and poured into cold water. Phosphorus oxychloride and any phosphorus pentachloride remaining were dissolved in the water, and after a time the oil hardened. It was broken up with a stirring rod and ground with fresh water in a mortar. Finally the powder was let stand in more water over night, filtered, and the solid dried over sulfuric acid in a desiccator. It was next dissolved in hot carbon tetrachloride, filtered, and let stand to crystallize. If the solution was concentrated, the unsymmetrical chloride crystallized first and later there were superimposed on the crystalline mass hard, glistening, rhombohedral crystals of the symmetrical chloride. These

<sup>1</sup> Remsen, *Am. Chem. J.*, 30, 247 (1903); List and Stein, *Ber.*, 31, 1648 (1898).

were picked out by hand from the mass. In another experiment it was found that this chloride crystallized in the form of long, white needles. Once these were produced in the laboratory, the rhombohedral forms never appeared again. The needles seemed to be less soluble than the unsymmetrical acid chloride, and hence could be taken out from the carbon tetrachloride solution as the first crop of crystals. In some cases the solution was seeded to bring about the rapid production of this form.

The identity of the two crystalline forms of the symmetrical acid chloride was shown by the identical melting points,  $134^{\circ}$ , and also by the fact that when the rhombohedral form was dissolved in carbon tetrachloride and a trace of the needles added, the whole amount present crystallized out in the needle form.

The symmetrical acid chloride was recrystallized from carbon tetrachloride several times until the melting point was constant at  $134^{\circ}$ , and then analyzed.

Calc. for Cl, 23.80; N, 4.70; S, 10.74. Found: Cl, 23.65, 24.02; N, 4.68, 4.64; S, 10.72.

**Unsymmetrical Acid Chloride,**  $\text{NO}_2\text{CH}_2\text{C}_6\text{H}_2$   $\begin{cases} \text{C} = \text{Cl}_2(1) \\ > \text{O} \\ \text{SO}_2(2) \end{cases}$ .—This acid

chloride constituted about five-eighths of the total yield of the acid chlorides as made by the open dish method. Its formation is apparently favored by the presence of phosphorus oxychloride, for when a reflux condenser is used in the preparation of the chlorides, and the condensed phosphorus oxychloride formed is kept in the mixture, a much larger percentage of the unsymmetrical chloride is produced, although the absolute yield seems to be smaller. Holmes<sup>1</sup> used phosphorus oxychloride in sealed tubes for the preparation of the pure unsymmetrical acid chloride of *p*-nitro-*o*-sulFOBenzoic acid. In this case we found it not necessary, and the shorter process was used.

The purification of the unsymmetrical acid chloride by fractional crystallization from carbon tetrachloride was not difficult. It crystallized in short, tufted, rather soft needles, yellowish in color. An attempt was made to use the method of List and Stein<sup>2</sup> for the purification of the acid chlorides by distillation *in vacuo*. It was expected that the symmetrical chloride would decompose at the distillation temperature, while the unsymmetrical would distil unchanged. Distillation took place at the following temperatures and pressures:

Pressure in mm. mercury.....	21	11	10
Boiling point.....	218–220°	214°	212°

No difference was observed in the melting point of the pure  $83^{\circ}$  melting point substance by the distillation.

<sup>1</sup> *Am. Chem. J.*, 25, 204 (1901).

<sup>2</sup> *Ber.*, 31, 1648 (1898).

The acid chloride melting at  $83^{\circ}$  was analyzed, the methods used being the same as in the case of the high melting chloride.

Calc. for Cl, 23.80; N, 4.70; S, 10.74.

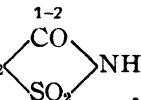

Found: Cl, 23.3, 23.4, 23.46; N, 4.82, 4.79; S, 10.77.

### Derivatives Obtained by the Action of Ammonia on the Acid Chlorides.

**A. From the Symmetrical Acid Chloride.**—A suitable amount of the acid chloride was placed in an open beaker and treated with concentrated ammonia. Apparently there was no action in the cold, but on raising the temperature slowly to boiling, so as to keep the concentration of the ammonia as high as possible, the acid chloride dissolved. When the excess of ammonia was evaporated off and the residue was cooled somewhat, the ammonium salt of the imide crystallized out as small glistening cubes. These were recrystallized from water several times. They then gave a melting point, with decomposition, of  $310-320^{\circ}$ . No other substance was recovered in the preparation except the ammonium chloride formed in the reaction. The symmetrical acid chloride is only slightly acted upon in nonaqueous solutions by ammonia.

Calc. for  $C_8H_9O_6N_3S$ : Total N, 16.21; Ammon. N, 5.40; S, 12.35.

Found: Total N, 16.20, 16.18; Ammon. N, 5.58; S, 12.38.

The Imide,  $NO_2.C\overset{4}{H}_3.C\overset{5}{H}_2$    $NH$ .—When the cold mother liquor

from the crystallization of the ammonium salt of the imide is made acid with hydrochloric acid, the imide separates almost quantitatively from the solution. It is colorless, and the crystals as viewed under the microscope are platelike needles. The insolubility of the precipitate makes it unnecessary to purify except by washing with water until free from chlorides. The imide is bitter tasting. It is readily soluble in alkali and forms salts with various metals by which it may be characterized more completely. Its melting point is  $213.5^{\circ}$ .

Calc. for N, 11.57; S, 13.22. Found: N, 11.77, 11.68; S, 13.25.

The *silver* salt of the imide,  $C_8H_5O_6SN_2Ag$ , was obtained by adding a solution of silver nitrate to a hot aqueous solution of the imide. It separates in platelike needles and is less soluble than the silver salt of the cyan-acid to be described later.

Calc. for Ag, 30.92. Found: Ag, 30.87.

The *potassium* salt of the imide was obtained by adding an excess of a concentrated potassium carbonate solution to an aqueous solution of the ammonium salt. It crystallizes in plates, and has a weak bitter taste.

Calc. for K, 13.96. Found: K, 13.91.

**B. From the Unsymmetrical Chloride.**—If the acid chloride melting at  $83^{\circ}$  is treated with cold concentrated ammonia, an action takes place

which, while beginning slowly, at last goes on rapidly with the evolution of heat. The behavior in this respect is characteristically different from that of the symmetrical chloride. In making the ammonia derivative in practice, the ammonia was diluted with three parts of water to lessen the action. If the ammonia is evaporated off and the remaining liquid is concentrated and cooled, crystals form in nodules. These crystals are not as sharply defined as those of the corresponding ammonium salt of the imide; the nodules appear to be made up of compact masses of radiating crystals which branch continually into fanlike shapes. When these nodules are crushed, it is impossible to find any characteristic crystalline form. Recrystallized from alcohol, however, the crystals were not bunched but seemed to be laminated plates almost cubical in form, but with no smooth surfaces. The yield of the product is good. In no case was there any indication of the ammonium salt of the imide. The salt is more soluble than the ammonium salt of the imide. Its melting point is  $310-311^{\circ}$ , with decomposition. It is the ammonium salt of 5-nitro-4-methyl-2-cyanbenzenesulfonic acid. It has a very bitter taste. The free acid was not prepared.

Calc. for  $C_8H_5O_6N_3S$ : N, 16.21; S, 12.35. Found: N, 16.11, 15.95; S, 12.31, 12.24.

The *silver salt*,  $C_8H_5O_6SN_2Ag$ , was prepared by adding a silver nitrate solution to a hot dilute aqueous solution of the ammonium salt. It forms needles and contains no water of crystallization.

Calc. for Ag, 30.92. Found: 30.81.

The *potassium salt*,  $C_8H_5O_6SN_2K$ , made from the ammonium salt and potassium carbonate, separates in plates with no water of crystallization. It has a bitter taste.

Calc. for K, 13.96. Found: 14.03.

### Derivatives Obtained by the Action of Aniline on the Acid Chlorides.

A. **From the Symmetrical Chloride.**—The formation of the anilides of the acid chlorides by previous experimenters in this field has been carried out in three ways: first, by the treatment of the solid acid chloride with aniline; second, by the treatment of the acid chloride with aniline in ether or chloroform solution; and third, by the action of aniline on the acid chloride in the presence of water. The first method has been found to be unsatisfactory. In general, the third method has been chosen by Remsen and his students as it seemed to give the most constant results. In this work, however, it has been found that by using carbon tetrachloride as the solvent the products were of the same nature as those obtained by the aqueous method. The process is shorter and the substances are easily separated from one another.

From the symmetrical acid chloride two products were obtained. One of these, which is insoluble in cold, reasonably dilute sodium hydroxide,

is known as the *anil*. It resembles the imide in many respects, but does not form salts as it contains no imido hydrogen. The other product is the *symmetrical dianilide*.<sup>1</sup>

The Anil,  $\text{NO}_2.\overset{4}{\text{CH}_3}.\overset{5}{\text{C}_6\text{H}_2} \begin{cases} \text{C} = \text{O} \text{ (1)} \\ > \text{N}.\text{C}_6\text{H}_5. \\ \text{SO}_2 \text{ (2)} \end{cases}$ —One gram of the symmet-

rical acid chloride was dissolved in about 50 cc. of carbon tetrachloride at boiling temperature. While this was hot there was added aniline in excess of the amount calculated for the dianilide. This aniline also was dissolved in carbon tetrachloride, and the mixture was warmed for an hour. There was only a slight precipitate at the end of that time, hence the carbon tetrachloride was evaporated and the residue treated with dilute hydrochloric acid. After kneading the residue, which at this stage was oily in nature, for several minutes, the mass solidified. It was then broken up into fine fragments and was allowed to stand overnight in order that the excess aniline might all dissolve as the hydrochloride. The residue was filtered, ground in a mortar with hydrochloric acid, filtered and washed with water to remove the excess of acid. It was next treated with cold, dilute potassium hydroxide. The solution became bright yellow, and a dirty white precipitate was left in an amount small as compared with the bulk of the original precipitate. This insoluble material, which was the anil, was washed with water, dried, and recrystallized from alcohol. The yield of crude anil was 0.27 g.

The anil is very insoluble in alcohol except close to the boiling point. About one hundred cc. of alcohol were required to recrystallize the anil as above. When pure, it is nearly white, and crystallizes in needles which have a melting point of 202–203°.

Calc. for N, 8.81. Found: N, 9.00.

The Symmetrical Anilide,  $\text{NO}_2.\overset{4}{\text{CH}_3}.\overset{5}{\text{C}_6\text{H}_2} \begin{cases} \text{CO.NHC}_6\text{H}_5 \text{ (1)} \\ \text{SO}_2.\text{NHC}_6\text{H}_5 \text{ (2)} \end{cases}$ —The

sodium hydroxide solution filtered from the anil was acidified with hydrochloric acid. A white, curdy precipitate at once came down and was filtered off and washed free from acid. It was then redissolved and reprecipitated for further purification. Finally, it was washed, dried, and recrystallized from 75% alcohol. It formed a fine, cottony mass of soft needles with a melting point of 195°. The yield of the anilide was 0.98 g. The substance was identified in this case not by analysis but by its exact correspondence with the dianilide formed under like conditions as a derivative of the unsymmetrical acid chloride. Mixtures of the two preparations showed the same melting point as that of either of the pure specimens.

<sup>1</sup> See Remsen and Kohler, *Am. Chem. J.*, 17, 338 (1895).

List and Stein<sup>1</sup> state that there are three products formed by the action of aniline on<sup>o</sup> the symmetrical chloride, but there was no indication of a third compound here, and a consideration of the yields obtained will show that no very large amount of the material is unaccounted for.

**B. From the Unsymmetrical Chloride.**—The unsymmetrical chloride was dissolved in carbon tetrachloride and to the hot solution was added a carbon tetrachloride solution of aniline so long as a white precipitate continued to form. Hydrochloric acid vapor was evolved copiously, and aniline hydrochloride apparently did not form to any great extent. The precipitate thus formed, on being stirred, gathered into a gummy mass which hardened as the solution cooled. The carbon tetrachloride solution was evaporated to dryness and the whole solid residue ground with hydrochloric acid in a mortar and then allowed to stand to remove soluble products. After some hours it was filtered and washed with a considerable amount of water. The insoluble precipitate was treated with dilute sodium hydroxide in which it was almost completely soluble. Only a faint cloudiness remained in the solution, hence but the merest traces of anil could have been formed. This corresponds with the observation by Holmes<sup>2</sup> that no anil was produced from the unsymmetrical chloride of *o*-sulfo benzoic acid. From this solution the anilide was precipitated by hydrochloric acid, washed, dried and recrystallized from alcohol. It was found, however, that a large portion of the precipitated material would not dissolve in hot alcohol. The insoluble portion proved to be the *unsymmetrical anilide* described later. The portion which dissolved gave needles which melted at 195°, and were the *symmetrical anilide*. It is tasteless, and identical with the anilide formed from the symmetrical acid chloride.

Calc. for N, 10.22; S, 7.78. Found: N, 10.15, 10.06; S, 7.91.

The substance insoluble in alcohol was purified by dissolving in hot 75% alcohol with the aid of sodium hydroxide added drop by drop until the precipitate had disappeared. To this solution acid was added, and the precipitate which formed after a delay of some seconds was nicely crystalline. The crystals were very fine. The melting point seemed to be at 342°; but fusion did not occur until after the product was quite black with heating.

The unsymmetrical anilide is insoluble in most ordinary solvents and this is a general characteristic of such substances. Carbon tetrachloride, alcohol and benzene have little, if any, action on it.

<sup>1</sup> *Loc. cit.*

<sup>2</sup> *Am. Chem. J.*, 30, 275 (1903).

Calc. for N, 10.22; S, 7.78. Found: N, 10.02; S, 7.77, 7.69.

A third substance is produced by the action of aniline on the unsymmetrical chloride. It is soluble in water and may be recovered from the various washings of the original dianilide by evaporation. It crystallizes in needles. It is suspected that this body is the anilido acid, but it is difficult to purify and no satisfactory analyses were obtained of it. While the total yields of the two anilides obtained from the unsymmetrical acid chloride were almost equal in amount, the weight of the third substance is considerably less than either.

#### Transformations of the Aniline Derivatives.

When either the symmetrical or unsymmetrical anilide is treated with phosphorus oxychloride, at boiling temperature, for about one-half hour, a yellow colored solution is produced. If the excess of phosphorus oxychloride is distilled off with care, an air blast being used to help the process, a thick, brownish oil is left, which after being cooled and treated with water to remove phosphoric acid, becomes a bright yellow

powder. This powder is the dianil,  $\text{NO}_2 \cdot \text{CH}_3 \cdot \text{C}_6\text{H}_2$   $\begin{cases} \text{C} = \text{NC}_6\text{H}_5 & (1) \\ > \text{NC}_6\text{H}_5 \\ \text{SO}_2 & (2) \end{cases}$ .

It crystallizes from dilute acetone in short, bright yellow, hexagonal needles. It is soluble in benzene and alcohol, and melts at 188°.

Calc. for N, 10.69; S, 8.14. Found: N, 10.76; S, 8.10.

When the dianil<sup>1</sup> is boiled with concentrated hydrochloric acid it goes over into the colorless anil without dissolving, and the yellow color slowly disappears during the process. The melting point of the colorless solid, 202°, shows it to be the anil.

If the dianil is boiled for some time with glacial acetic acid until the solution, which is vivid yellow at first, becomes colorless, and the solution is allowed to stand, the unsymmetrical anilide crystallizes out. When washed with water and dried it has a melting point of approximately 342°, as described previously.

If the anil is warmed with aniline for some hours, and the excess of aniline distilled off with steam, the residue when recrystallized from alcohol, proves to be the fusible or symmetrical anilide with a melting point of 195°.

#### Derivatives Obtained by the Action of Alcohol on the Acid Chlorides.

In all of the experiments with the alcoholic derivatives of the two acid chlorides, the final products are the same, the only difference being the formation of the ester of the sulfone chloride as an intermediate product in the action of the alcohol on the unsymmetrical acid chloride.\*

<sup>1</sup> See Blanchard, *Am. Chem. J.*, 30, 485 (1903); Henderson, *Ibid.*, 25, 1 (1901).

<sup>2</sup> See Kastle, *Am. Chem. J.*, 11, 181 (1889); Sohon, *Ibid.*, 20, 260 (1898); Henderson, *Ibid.*, 25, 8 (1901); Chambers, *Ibid.*, 30, 387 (1903).

**Methyl Ester Sulfone Chloride**,  $\text{NO}_2\text{.CH}_3\text{.C}_6\text{H}_2\text{.COOCH}_3\text{.SO}_2\text{Cl}$ .—This substance was prepared from the unsymmetrical acid chloride by dissolving in hot methyl alcohol. The warming was kept up only long enough to obtain solution. When the solution was cooled, the sulfone chloride ester separated in long, platelike crystals which were recrystallized from ligroin. It is very soluble in benzene, alcohol, acetone, ether and chloroform. After standing overnight in a desiccator, the product, which has a melting point of  $101^\circ$ , was analyzed.

Calc. for N, 4.77; S, 10.92; Cl, 12.08.

Found: N, 4.66, 4.61; S, 10.75, 11.02; Cl, 12.09, 12.01.

The *ethyl ester sulfone chloride* was also prepared and analyzed. It melts at  $72^\circ$ .

**Methyl Benzoic Ester of the Sulfonic Acid**,  $\text{NO}_2\text{.CH}_3\text{.C}_6\text{H}_2\text{.COOCH}_3\text{.SO}_2\text{OH}$ .—The methyl ester acid was prepared by boiling either acid chloride with methyl alcohol for some time and evaporating to a syrup. On cooling, it slowly formed crystals which, on account of their extreme solubility, were not purified. The identification was by means of the barium salt, which could be made easily. The silver salt, which was very soluble, was made but not analyzed. It was used in the preparation of the dimethyl ester. The barium salt contains no water of crystallization, and gave the following result upon analysis:

Calc. for Ba, 20.04. Found: Ba, 20.05.

The *ethyl benzoic ester* was also prepared.

**The Dimethyl Ester**,  $\text{NO}_2\text{.CH}_3\text{.C}_6\text{H}_2\text{.COOCH}_3\text{.SO}_2\text{OCH}_3$ .—The dimethyl ester cannot be made by the direct action of the acid chlorides on alcohol. Neither does the action of sodium methylate,<sup>1</sup> either dry or in absolute alcohol, upon an absolute ether solution of the acid chloride prove of much value. The best method was that of treating the silver salt of the methyl ester acid with methyl iodide in a pressure bottle as recommended by Kastle.<sup>2</sup> After heating the mixture some time at  $100^\circ$  the excess of methyl iodide is evaporated off and the residue extracted with absolute ether. The product obtained by evaporating the ether and recrystallizing from absolute methyl alcohol melted at  $94.5^\circ$ . It is insoluble in water, has a neutral reaction, and contains no halogen.

Calc. for N, 4.85. Found: N, 4.98.

#### Derivatives Obtained by the Action of Phenol on the Acid Chlorides.

The action of phenol upon the acid chlorides is of the same general nature as that given by the alcohols. Both acid chlorides seem to give

<sup>1</sup> Cobb, *Am. Chem. J.*, 35, 488 (1908).

<sup>2</sup> *Loc. cit.*

practically the same derivatives,<sup>1</sup> the relative amounts of which depend upon the temperature. At the same time there is usually formed a water-soluble red substance, probably a phthalein, which has not been investigated.

The **Diphenyl Ester**,  $\text{NO}_2\text{CH}_3\text{C}_6\text{H}_2\text{COOC}_6\text{H}_5\text{SO}_2\text{OC}_6\text{H}_5$ .—Three methods were used in preparing the diphenyl ester. First, the acid chloride was warmed with phenol. The production of phthalein was so marked that this method was used only for a trial preparation. The di-ester appears to be the only product outside of the phthalein.

Second, the Schotten-Baumann method was tried. The acid chloride was dissolved by gentle warming in a slight excess of phenol and dilute potassium hydroxide solution. The yellow oil which first formed soon solidified and was recrystallized from organic solvents. The amount of phthalein formed was small.

The third method consisted of treating the acid chloride with a mixture of pyridine and phenol. Two grams of phenol and an equal amount of pyridine were mixed in a small beaker and the powdered acid chloride added.

When the acid chloride had dissolved in the pyridine phenol solution the liquid was allowed to stand at room temperature for the completion of the reaction. Alcohol was then added and warmed until all the compound was in solution. As the liquid cooled, crystals formed as colorless, flat needles somewhat resembling those of the ethyl benzoic ester of the sulfone chloride. These contained no chlorine, however, and were the diphenyl ester. The melting point of the crude product is, according to our experience, always  $115^\circ$  or  $116^\circ$ , but by recrystallization from alcohol, benzene, alcohol, glacial acetic acid, and alcohol in the order named, the melting point becomes constant at  $123^\circ$ . The products which were obtained separately from the symmetrical and unsymmetrical acid chlorides are identical in this respect as in all others. No sulfone chloride was formed by any of these three methods, a fact which was due in all probability to the temperature employed.

Calc. for N, 3.39; S, 7.75. Found: N, 3.42, 3.47; S, 7.74, 7.86.

### Summary.

1. Two acid chlorides, the symmetrical with a melting point of  $134^\circ$ , the unsymmetrical with a melting point of  $83^\circ$ , have been prepared. These compounds were peculiar only in that they could be separated by fractional crystallization from solution, and that when pure, they did not tend in the least to form constant melting-point mixtures. Two crystalline forms of the symmetrical acid chloride were isolated, but their differences were not investigated closely.

<sup>1</sup>Humphreys, *Am. Chem. J.*, 30, 292 (1903); Chambers, *Ibid.*, 30, 374 (1903).

2. The derivative obtained by the action of ammonia upon the symmetrical acid chloride was the ammonium salt of the imide. From this the imide itself was prepared by the action of dilute hydrochloric acid. The silver salt and the potassium salt of the imide also were made and analyzed.

3. The derivative obtained by the action of ammonia on the unsymmetrical acid chloride was the ammonium salt of the cyan acid; no imide was found. The silver and potassium salts of the cyan acid also were made and analyzed.

4. The derivatives obtained by the action of aniline on the symmetrical acid chloride were the symmetrical dianilide and the anil.

5. The derivatives obtained by the action of aniline on the unsymmetrical acid chloride were the symmetrical dianilide and the unsymmetrical dianilide.

6. By the action of phosphorus oxychloride, each of the two dianilides was transformed into the dianil. This in turn when heated with concentrated hydrochloric acid gave the anil or, heated with glacial acetic acid it gave the unsymmetrical dianilide.

7. The derivative obtained by the action of the alcohols on the symmetrical acid chloride was the benzoic ester of the sulfonic acid.

8. The derivatives obtained by the action of alcohols on the unsymmetrical acid chloride were the benzoic ester of the sulfone chloride, and the benzoic ester of the sulfonic acid.

9. The derivative obtained by the action of phenol upon either of the acid chlorides was always the diphenyl ester. No particular effort was made to prepare the phenyl sulfone chloride. When pyridine was used in the reaction, a second substance was formed which may be the pyridine salt of the phenyl benzoic ester acid. Its constitution was not established.

10. By the action of methyl iodide on the silver salt of the methyl benzoic ester acid, the dimethyl ester was formed.

<sup>1</sup> The experimental work upon which this paper is based was carried out by Mr. Tuttle in partial fulfilment of the requirements for the degree of Doctor of Philosophy under the Faculty of Pure Science of Columbia University.

***p*-Cymene 2-Monocarboxylic Acid. *p*-Cymene 3-Monocarboxylic Acid.**

**I. *p*-Cymene 2-Monocarboxylic Acid.**—Paterno and Fileti,<sup>1</sup> in 1875, fused cymene sodium sulfonate with potassium cyanide and saponified the dark colored crude product with alcoholic potassium hydroxide solution, obtaining what was apparently the amide (m. 138–9°, corr.) of the cymene 2-carboxylic acid.

Four years later, Paterno and Spica,<sup>2</sup> by hydrolysis of this amide, secured what they believed to be the cymene carboxylic acid itself as a solid crystallizing from water in fine needles, m. 63°, but failed to get enough pure material for an analysis. They also endeavored to prepare this acid by the fusion of the corresponding cymene sodium sulfonate with sodium formate, and by the action of CO<sub>2</sub> and metallic sodium upon bromocymene, but were unsuccessful in both cases.

Kreysler<sup>3</sup> heated tricarvacryl phosphate with potassium cyanide and obtained, in an impure form, the nitrile of the desired acid. By heating this nitrile with alcoholic potassium hydroxide solution under pressure and purifying the product, an acid was isolated which on analysis gave figures agreeing with those calculated for cymene carboxylic acid. He described his product as forming colorless needles, m. 75°, and also prepared a silver salt.

In 1886, Cropp<sup>4</sup> described as a cymene monocarboxylic acid a substance m. 272° resulting from the oxidation of methyl *p*-cymyl ketone. Murtfeld,<sup>5</sup> in the following year, obtained an acid, m. 272°, by oxidation of di-*p*-cymyl ethylene diketone with dilute nitric acid at 150°, which he regarded as a cymene monocarboxylic acid and as probably identical with the acid mentioned by Cropp. Claus,<sup>6</sup> however, later showed that the supposititious cymene carboxylic acid of Cropp and Murtfeld was in all probability a mixture consisting mainly of methyl isophthalic acid (m. 320–330°).

Claus,<sup>7</sup> and Neukranz<sup>8</sup> by careful oxidation of methyl *p*-cymyl ketone

<sup>8</sup> *Inaug. Diss.*, Freiburg, 1891.

with potassium permanganate, obtained a small amount of the cymene 2-carboxylic acid in small, colorless needles, m.  $69^{\circ}$  (uncorr.), which they stated sublimed in crystals when heated. In addition to the free acid, Neukranz prepared also the K, Ba, Ca, Cu and Ag salts, as well as an impure sodium salt. So far as we have been able to discover, these salts have never been described in any of the chemical journals and appear only in the above dissertation.

To sum up: small amounts of the free acid have been obtained hitherto and its m. p. has been given by these investigators as  $63^{\circ}$ ,  $69^{\circ}$  or  $75^{\circ}$ ; K, Ba, Ca, Cu, Ag and an impure Na salt have been described; also an amide and an impure nitrile.

The original work reported in the Experimental Part includes a method for preparing this acid in any desired amount from 2-bromocymene by the Barbier-Grignard reaction, a study of various salts and of the amide, the preparation and characterization of the hitherto unknown methyl and ethyl esters, the acid chloride, anilide, diacyl hydrazine,  $\alpha, \alpha'$ -dicymyl-[*bb*]-furodiazole, 2-methyl-5-isopropylhippuric acid and its ethyl ester. Preliminary studies have also been made upon the bromination of the free acid.

The furodiazole was easily obtained by the dehydration of the di-acyl hydrazine, as follows:

and the hippuric acid derivative by condensing the acid chloride with glycine ester,

Incidentally, the experiments showed that the bromocymene produced by direct bromination of the hydrocarbon is not, as has been supposed hitherto, pure 2-bromocymene; but generally contains some of the 3-bromo isomer also, which cannot be separated by any ordinary fractional distillation.

The process of Paterno and Fileti, and of Paterno and Spica, has been repeated, and it has been found that the acid so obtained was an impure cymene 2-monocarboxylic acid.

**II. *p*-Cymene 3-Monocarboxylic Acid.**—Our search of the literature has so far failed to disclose any record of this acid or of any of its derivatives. The only reference to attempts to prepare it, appears to be the statement of Kreysler<sup>1</sup> that he endeavored unsuccessfully to obtain it by distilling tri-thymyl phosphate with potassium cyanide and saponi-

<sup>1</sup> *Loc. cit.*

fying the product; but he failed to get either the pure nitrile or sufficient of the acid to analyze or identify.

In the Experimental Part is recorded the synthesis of this acid from 3-bromocymene by the Barbier-Grignard reaction; also the preparation of its Na, K, Ba, Ca, Cu and Ag salts; its methyl, ethyl and phenyl esters, acid chloride, amide, anilide, and diacyl hydrazine; and, from the latter, the  $\alpha, \alpha'$ -dicymyl- $[bb_1]$ -furodiazole and N-phenyl- $\alpha, \alpha'$ -dicymyl- $[bb_1]$ -pyrroldiazole; and the 3-methyl-6-isopropylhippuric acid from the acid chloride and glycine.

The yield of both cymene carboxylic acids was greatly increased by employing  $\text{CO}_2$  under pressure, and a "Prana" carbonating siphon proved most convenient for the purpose.

#### EXPERIMENTAL PART.

##### I. *p*-Cymene 2-Monocarboxylic Acid.

**Cymene.**—The cymene used in these experiments was purified by the following process: (1) fractional distillation at ordinary pressure, (2) digestion with metallic sodium or phosphoric anhydride, (3) fractional distillation under reduced pressure, and (4) finally repeated rectification over metallic sodium at ordinary pressure. In spite of this, we failed to get a constant and unvarying boiling point, the purified hydrocarbon generally showing a corrected b. p. varying between the limits  $176.5^\circ$  and  $178^\circ$  at ordinary pressure. Density and refractive index determined on different lots showed the following range:  $D_{15} \ 0.8615$  to  $0.8622$ ;  $N_D^{20} \ 1.4883$  to  $1.4897$ . This refractive index agrees with that calculated for the sodium line from the figures given by Perkin<sup>1</sup> for pure cymene at  $4^\circ$ , namely  $\mu \ 7.9^\circ/4^\circ = 1.49664$ . Assuming that the difference for  $1^\circ$  is approximately that for benzene, namely  $0.00066$ , then  $N$  at  $20^\circ$  would be  $1.49664 - 0.00799 = 1.48865$ . Examined in a 200 mm. tube, the hydrocarbon showed no trace of rotation.

*2-Bromocymene* has been prepared by the direct bromination of cymene, in presence of small amounts of iodine as catalyst, by Landolph,<sup>2</sup> Fittica,<sup>3</sup> and by Remsen and Day;<sup>4</sup> by Kelbe and Koschnitzky,<sup>5</sup> by warming cymene sulfo acid with bromine water; and by Klages and Kraith<sup>6</sup> by the action of  $\text{PBr}_5$  upon carvone. The b. p. is variously stated by these investigators as  $228-9^\circ$  (Fittica),  $233^\circ$  (Klages and Kraith)  $233-5^\circ$ , (in vapor) (Landolph), and  $237^\circ$  (corr.) (or  $228-9^\circ$ , uncorr.) (Remsen and Day).

According to our experiments, the most convenient method of prepara-

<sup>1</sup> *J. Chem. Soc.*, 77, 279 (1900).

<sup>3</sup> *Ann.*, 172, 311 (1874).

<sup>4</sup> *Am. Chem. J.*, 5, 150 (1883).

<sup>5</sup> *Ber.*, 19, 1732 (1886).

<sup>6</sup> *Ibid.*, 32, 2557 (1899).

tion proved to be the following: Bromine (about 10% excess) was added very gradually to pure cymene containing a small amount of iron powder as catalyst, the reaction being carried out in a flask protected from strong daylight, and cooling when necessary to moderate the reaction. The mixture was then warmed on the water bath, the HBr and excess of bromine blown out by a current of dry air, the crude product washed with water, digested with warm sodium carbonate solution, washed again with water, distilled with steam, the oily layer separated from the distillate, dried over calcium chloride, and fractioned under reduced pressure. The fraction b. 116.5–118.5° at 14.7 mm. (corr.) was employed in the subsequent experimental work. The yield of this purified material from 915 g. cymene amounted to 630 g. and its uncorrected b. p. at ordinary pressure was 231–3°.

The use of an excess of bromine was found to increase the yield of bromocymene, whereas the length of time the reaction mixture was allowed to stand after the addition of the bromine did not appear to influence the yield materially. Iron powder proved a much more active catalyst than iodine for this reaction. Fractionation under diminished pressure was necessary, as some decomposition occurred at the ordinary pressure. No unchanged cymene was found in the product, and the purified substance was colorless with a pleasant odor somewhat recalling that of cymene itself. The subsequent work with this product, however, proved conclusively that it was contaminated with the 3-bromo isomer, and the boiling points of the two lie so close together that it was impossible to separate them by fractional distillation.

Some 2-bromocymene was, therefore, prepared also by the action of PBr<sub>3</sub> upon purified carvacrol, in practically the same way as Fileti and Crosa<sup>1</sup> made the 3-bromo isomer from thymol. The yield was not very good, as considerable of the phenol remains behind as a phosphoric ester (from which it can be recovered if desired). 57 g. carvacrol gave 8.6 g. of the 2-bromocymene, b. 232–5° (uncorr.).

Large amounts of bromocymene can be prepared easily by the direct bromination of the hydrocarbon, as described above, but the product is a mixture of the two isomers. On the other hand, it is not very convenient to prepare large amounts of 2-bromocymene from carvacrol, but the product so obtained is free from the 3-bromo isomer.

**Cymene 2-Carboxylic Acid.**—In view of Landolph's observation<sup>2</sup> that the bromine in 2-bromocymene does not react with metallic sodium, alone or in the presence of methyl iodide or CO<sub>2</sub>, it was to be expected that it would prove somewhat unreactive even with magnesium, and this was found to be the case not only with this particular bromocymene

<sup>1</sup> *Gazz. chim. ital.*, 16, 292 (1886).

<sup>2</sup> *Loc. cit.*

but also with the isomeric 3-bromo compound. An anhydrous ethereal solution of either compound showed no evidence of any reaction upon boiling with metallic magnesium for about an hour, even after the addition of small amounts of iodine. To activate the magnesium, it was found advantageous to add a few drops of ethyl iodide. If, then, after a few minutes' standing, the anhydrous ether solution of bromocymene was added, the mixture being warmed, the reaction began immediately and proceeded to completion without further external heating, the bromocymene solution being added gradually from time to time. When the latter had all been added, the solution was heated for a short time on the water bath, when the magnesium almost wholly dissolved. The solution was cooled, and siphoned carefully into a "Prana" carbonating flask in such a way as to avoid contact with the moisture of the air, both containers being protected by calcium chloride guard tubes. The Prana flask was kept in a freezing mixture, and the solution therein treated with  $\text{CO}_2$  under pressure for several hours, using capsules of the liquid gas. This caused the mixture to separate into a clear upper ethereal layer and a lower darker one. The contents of the flask were decomposed with ice and dilute hydrochloric acid in the usual way, extracted with ether, the ether solution extracted in turn with sodium carbonate or potassium hydroxide solution, the alkaline solution concentrated somewhat, acidified with dilute hydrochloric acid, the white precipitate filtered out, washed, dried, and recrystallized. The yield of pure acid amounted to about 35%, when a pure 2-bromocymene was used. If the  $\text{CO}_2$  was not used under pressure, the yield was much less.

The 2-bromocymene used in the early experiments was made from carvacrol, so as to avoid complications due to the presence of the isomer. In a sample experiment, 8.6 g. of the bromocymene and 1 g. magnesium, yielded 2.7 g. of the crude acid, or about 40% of the theoretical. A small amount of cymene was usually formed in the reaction.

The crude acid was purified by dissolving it in about its own weight of glacial acetic acid, adding water until the solution clouded, warming until it cleared, and then allowing the solution to cool slowly, finally in the ice box. It can be crystallized also from dilute alcohol, but the crystals are not usually so fine as those secured by the above method.

The pure acid forms large, colorless, brittle, glassy prisms, m.  $71.7^\circ$  (corr.), difficultly soluble in cold water, slightly in hot; soluble in methyl or ethyl alcohol, ether, ligroin, benzene, xylene, chloroform, carbon tetrachloride, acetone, carbon disulfide, glacial acetic acid or ethyl acetate. It volatilizes slowly with steam, but does not sublime, contrary to the statement of Claus and Neukranz.<sup>1</sup> It can be distilled under reduced

<sup>1</sup> *Loc. cit.*

pressure, and boils at about  $171-2^{\circ}$  at 20 mm. Distilled with excess of soda lime,<sup>1</sup> it gives cymene again.

The following analysis was made of a sample of purified acid prepared from cymene:

Subs. 0.1662:  $\text{CO}_2$ , 0.4515;  $\text{H}_2\text{O}$ , 0.1137. Calc. for  $\text{C}_{11}\text{H}_{14}\text{O}_2$ : C, 74.16; H, 7.87. Found: C, 74.09; H, 7.60.

Cryoscopic molecular weight determinations in acetic acid gave the figures 171 and 176, while the calculated molecular weight is 178.

The preparation of pure 2-acid from the bromocymene obtained from cymene proved very troublesome, on account of the presence of the 3-isomer. In one experiment, for example, a mixture of 200 g. bromocymene, 23 g. magnesium and 400 cc. anhydrous ether, was treated for about  $10\frac{1}{2}$  hours with  $\text{CO}_2$  under pressure, supplying the latter as fast as it was absorbed. In all, a total of 68 g. liquid  $\text{CO}_2$  was used, the amount theoretically required being about 40 g. The reaction was conducted at a temperature of  $-13^{\circ}$  to  $-3^{\circ}$ . 60 g. of crude acid were obtained, as a yellowish semi-solid mass, which proved very difficult to purify. By fractional crystallization, only 30 g. of pure 2-acid could be recovered. The mother-liquors were united, the acid neutralized with sodium carbonate, the solution filtered, washed with ether, warmed to eliminate any dissolved ether, and then fractionally precipitated with dilute hydrochloric acid. The 2-acid was found in the first fractions, the 3-acid in the later ones, the intermediate fractions being mixtures of the two.

In another experiment, 230 g. bromocymene and 27 g. magnesium were used, and the crude acid was distilled under reduced pressure. 105 g. of impure 2-acid resulted, from which by filtering and pressing 79 g. solid acid were obtained. When these 79 g. were converted into the sodium salt and the solution of the latter precipitated fractionally by dilute hydrochloric acid, 36 g. pure 2-acid and 9 g. pure 3-acid were recovered.

**Sodium Salt, NaA.**—This was prepared in the same way as described below for the potassium salt. It does not crystallize well, but forms a white powder, without water of crystallization, and is not hygroscopic.

Subs. 0.3190:  $\text{Na}_2\text{SO}_4$ , 0.1105. Calc. for  $\text{C}_{11}\text{H}_{13}\text{O}_2\text{Na}$ : Na, 11.50. Found: Na, 11.23.

Neukranz<sup>1</sup> prepared a sodium salt, which on analysis was found to contain 23.22% sodium, and which must, therefore, have been very impure. Apparently, his calculations misled him, as he puts down for the calculated percentage of sodium in this salt 23.5, whereas as a matter of fact it is 11.5, as stated above.

**Potassium Salt, KA.H<sub>2</sub>O.**—A 5% aqueous solution of potassium hydroxide was treated with a slight excess of the 2-acid, the mixture allowed to stand for a few hours and the excess of free acid (which is prac-

<sup>1</sup> *Loc. cit.*

tically insoluble in cold water) then filtered off. The filtrate was concentrated on the water bath to a paste and then placed in a desiccator where it gradually became crystalline. It carries one molecule of water of crystallization, but is not appreciably hygroscopic.

0.2550 g. salt dried to constant weight in desiccator over  $\text{H}_2\text{SO}_4$ , and then heated to constant weight at  $115^\circ$ , lost 0.0194 g. Calc. for  $\text{C}_{11}\text{H}_{13}\text{O}_2\text{K}\cdot\text{H}_2\text{O}$ :  $\text{H}_2\text{O}$ , 7.69. Found:  $\text{H}_2\text{O}$ , 7.61.

Anhydrous salt, 0.2845:  $\text{K}_2\text{SO}_4$ , 0.1142. Calc. for  $\text{C}_{11}\text{H}_{13}\text{O}_2\text{K}$ : K, 18.09. Found: K, 18.03.

It forms small, colorless, glassy crystals. Neukranz makes no mention of any water of crystallization in the potassium salt he prepared.

**Calcium Salt,  $\text{CaA}_2\cdot 2\text{H}_2\text{O}$ .**—This was made in the same manner as the barium salt below. In water, it is much less soluble than the latter, and but little more soluble in hot water than in cold. Upon evaporation of the aqueous solution, the salt separates gradually in fine colorless crystals, which were dried in a desiccator.

Heated to const. wt. at  $105\text{--}10^\circ$ , the salt lost 8.32%. Calc. for  $2\text{H}_2\text{O}$ : 8.37%.

Anhydrous salt, 0.2765:  $\text{CaSO}_4$ , 0.0952. Calc. for  $(\text{C}_{11}\text{H}_{13}\text{O}_2)_2\text{Ca}$ : Ca, 10.15. Found: Ca, 10.12.

Neukranz also reports the calcium salt as containing two molecules of water of crystallization.

**Barium Salt,  $\text{BaA}_2$ .**—The acid was suspended in water and digested with excess of  $\text{BaCO}_3$  at  $100^\circ$  for three or four hours. It was then filtered, the filtrate again digested with  $\text{BaCO}_3$ , to make sure that all acid was converted into the salt, and once more filtered. The filtrate was concentrated until the salt began to separate and was then left in a desiccator over  $\text{H}_2\text{SO}_4$  for several days, where it slowly solidified. Dried at  $105\text{--}110^\circ$ , and then for two hours at  $120\text{--}5^\circ$ , it lost 1.5% in weight, whereas the loss calculated for one molecule water is 3.42. Evidently the salt either crystallizes without water of crystallization, or else this water is lost partly when the salt is left for a few days over  $\text{H}_2\text{SO}_4$ .

Anhydrous salt, 0.3584:  $\text{BaSO}_4$ , 0.1687. Calc. for  $(\text{C}_{11}\text{H}_{13}\text{O}_2)_2\text{Ba}$ : Ba, 27.90. Found: Ba, 27.70.

The barium salt isolated by Neukranz carried two molecules of water.

The **Copper Salt,  $\text{CuA}_2$** , was prepared by warming a solution of the calcium salt with an excess of copper acetate solution. A voluminous blue precipitate resulted. It was filtered out, washed and dried over  $\text{H}_2\text{SO}_4$ . As no loss of weight occurred at  $120^\circ$ , the salt carries no water of crystallization.

Calc. for  $(\text{C}_{11}\text{H}_{13}\text{O}_2)_2\text{Cu}$ : Cu, 15.23. Found: Cu, 15.62.

This high figure for the copper is probably due to the presence of a little adsorbed copper acetate, as the voluminous precipitate was not easily washed.

Neukranz reports a copper salt carrying one molecule of water of crystallization.

The **Silver Salt**, AgA, was prepared by dissolving the acid in ammonium hydroxide solution, warming to remove all excess of ammonia, and then adding silver nitrate solution. The acid used was obtained from carvacrol, and the salt was, therefore, analyzed completely, as a check upon the accuracy of the work.

Subs. 0.2155, 0.2350: Ag, 0.0814; CO<sub>2</sub>, 0.4012; H<sub>2</sub>O, 0.0946.

Calc. for C<sub>11</sub>H<sub>13</sub>O<sub>2</sub>Ag: Ag, 37.87; C, 46.33; H, 4.56. Found: Ag, 37.77; C, 46.52; H, 4.47.

It is a colorless, crystalline powder, which darkens on standing in the light, and has been prepared also by Kreyser<sup>1</sup> and by Neukranz.

**Methyl Ester**, C<sub>10</sub>H<sub>13</sub>COOCH<sub>3</sub>.—Three grams of methyl alcohol were dissolved in 25 cc. pyridine and 9.5 g. of the chloride of cymene 2-carboxylic acid added gradually with cooling and shaking. The reaction liberated considerable heat, but no precipitate separated until the last few drops of the acid chloride were being run in, when it began to form rapidly and in large amount. After standing for five hours, the mixture was poured into well cooled dilute sulfuric acid. A colorless oil separated, which was removed, washed four times with acidulated water to eliminate all pyridine, then with dilute potassium hydroxide solution to remove any free 2-acid (of which there proved to be very little), after which it was collected with ether, the ethereal solution washed, dried, the ether distilled off and the residue fractioned at a pressure of 16.2 mm. (corr.), the ester coming over at 132°, as a colorless oil of pleasant odor.

Subs. 0.1150: CO<sub>2</sub>, 0.3157; H<sub>2</sub>O, 0.0860. Calc. for C<sub>12</sub>H<sub>16</sub>O<sub>2</sub>: C, 75.00; H, 8.33. Found: C, 74.87; H, 8.31.

The **Ethyl Ester** was obtained by dissolving the acid in a slight excess of potassium hydroxide solution, and then digesting with diethyl sulfate, essentially as described beyond for the ethyl ester of the 3-acid.

It is a colorless heavy oil of pleasant ethereal odor, which can be saponified readily to the acid by alcoholic potassium hydroxide solution.

**Acid Chloride**, C<sub>10</sub>H<sub>13</sub>.CO.Cl.—The anhydrous acid was treated, in a flask provided with a calcium chloride guard tube, with slightly more than the calculated amount of PCl<sub>5</sub>. Upon shaking the mixture, the reaction began almost immediately and proceeded so vigorously that within two or three minutes, with the exception of a small amount of PCl<sub>5</sub>, the whole mass was liquid and quiescent. After standing for three-quarters of an hour, it was warmed for 15 minutes at 100°, when the small amount of undissolved PCl<sub>5</sub> went into solution, and was then transferred to a distilling flask and fractioned under reduced pressure, the acid chloride coming over as a clear colorless liquid of pungent odor, b. 131.5–132°

<sup>1</sup> *Loc. cit.*

at 17.7 mm., or 135.5–136° at 21.5 mm. The yield was usually better than 90%. In one experiment, for example, 21 g. acid gave 23.5 g. of the chloride.

**Acid Amide,  $C_{10}H_{13}.CO.NH_2$ .**—Prepared from the acid chloride, in practically the same way as described beyond for the amide of the 3-acid, this substance crystallizes from ligroin, water or dilute alcohol, in microscopic needles which felt together like shredded asbestos, and m. 147° (corr.). It is soluble in methyl alcohol, ethyl alcohol, or warm benzene; slightly soluble in ether or in cold carbon tetrachloride; insoluble in cold, slightly soluble in hot ligroin. Yield, 95%.

Subs. 0.1878: 12.7 cc. N at 21° and 762 mm. Calc. for  $C_{11}H_{15}ON$ : N, 7.91. Found: N, 7.69.

An attempt to convert this amide into the phenyl hydrazide by heating it for 2½ hours at 150–160° with phenyl hydrazine failed, the amide being recovered practically unchanged.

**Acid Anilide,  $C_{10}H_{13}.CO.NHC_6H_5$ .**—This was obtained from the acid chloride and aniline, in anhydrous ether solution, as outlined beyond for the anilide of the 3-acid. Yield, 87%.

The pure substance crystallizes from ligroin or dilute alcohol in small, colorless, glassy prisms, m. 143.5° (corr.); soluble in methyl or ethyl alcohols, in benzene, chloroform, acetone or amyl acetate; but slightly soluble in ether, hot water or cold ligroin; fairly soluble in cold carbon disulfide or carbon tetrachloride, easily soluble in the same hot.

Subs. 0.2521: 12.4 cc. N at 21° and 756 mm. Calc. for  $C_{17}H_{19}ON$ : N, 5.53. Found: N, 5.54.

**Sym.-2,2'-Dimethyl-5,5'-diisopropyl Dibenzoylhydrazine,  $C_{10}H_{13}.CO.NH.NH.CO.C_{10}H_{13}$ .**—In the production of this diacyl hydrazine, both the ordinary 50% aqueous solution of hydrazine hydrate was employed and also the more concentrated solution obtained by distilling the former until the temperature of the distillate reached 115°, when the residue is stated<sup>1</sup> to contain 55–60% of absolute  $N_2H_4$  or 90% of  $N_2H_4.H_2O$ . The results secured with the 50% aqueous solution were just as good as those with the more concentrated solution.

In a typical experiment, 13.5 g. acid chloride were dissolved in 4 cc. absolute ether and the solution added very gradually with shaking to an excess (approximately 4 mols) of well cooled hydrazine hydrate solution. A white precipitate began to separate immediately and slowly increased in amount. After all the acid chloride had been added (about an hour), the mixture was a white, pasty mass of strong alkaline reaction, due to the excess of hydrazine hydrate present. After standing for three hours, it was filtered, the precipitate washed thoroughly with cold

<sup>1</sup> Curtius, *J. prakt. Chem.*, [2] 42, 523 (1890).

water, dried, and crystallized from dilute alcohol.<sup>1</sup> Yield, 91% (11 g.).

The pure substance crystallizes in minute, colorless, glassy prisms, m. 192° (corr.); insoluble in ligroin or water; moderately soluble in chloroform or acetic acid; little soluble in ether or in cold alcohol, benzene or acetone, but readily soluble in the latter at their b. p. It forms no salts with hydrochloric or nitric acids, even in non-aqueous solvents.

Subs. 0.2341 g.: 16.8 cc. N at 21° and 754 mm. Calc. for  $C_{10}H_{12}.CO.NH.NH.CO.C_{10}H_{12}$ : N, 7.95; for  $C_{10}H_{12}.CO.NH.NH_2$ : N, 14.56. Found: N, 8.07.

An attempt was made to secure the monacyl hydrazine by heating the amide with excess of hydrazine hydrate alone, and in alcoholic solution, but the amide was recovered unchanged in both cases.

The diacyl hydrazine is unattacked by nitrous acid in glacial acetic acid solution.

The diacyl hydrazine was heated for an hour and three-quarters at 260–80° (thermometer in melt), and then cooled. The cold melt was purified by repeated crystallization from methyl alcohol in presence of boneblack.

The pure compound forms small, colorless, glassy prisms, m. 111.5° (corr.), quite soluble in benzene or chloroform, less so in benzine or acetone; slightly soluble in cold methyl alcohol or ethyl alcohol; and practically insoluble in water.

Subs. 0.1579: 11.83 cc. N at 21° and 752 mm. Calc. for  $C_{22}H_{28}ON_2$ : N, 8.38. Found: N, 8.40.

An effort was made to get the corresponding thiodiazole by the action of  $P_2S_5$  upon the diacyl hydrazine, but the product was a mixture of furo- and thiodiazole, from which we failed to isolate any really pure thiodiazole.<sup>2</sup>

**2-Methyl-5-isopropyl Hippuric Acid and its Ethyl Ester,  $C_{10}H_{12}.CO.NH.CH_2.COOH$ .**—35 g. of the acid chloride were added slowly, with cooling and shaking, to an excess of glycine ester in ethereal solution. A white precipitate separated. After standing at laboratory temperature for three hours, the white precipitate of glycine ester hydrochloride was filtered out, and the ethereal filtrate evaporated, leaving an oily residue,

<sup>1</sup> Compare also Pellizzari, *Atti r. Accad. Lincei Roma* [5] 8, I, 327; *Chem. Zentralbl.*, 1899, I, 1240; Stollé, *J. prakt. Chem.*, [2] 69, 474 (1904).

<sup>2</sup> Compare also Stollé, *J. prakt. Chem.*, [2] 69, 157, 374 (1904); Stevens, *Inaug. Diss.*, Heidelberg, 1899.

which was washed with dilute hydrochloric acid to remove any glycine ester present, taken up again with ether, the ethereal solution washed with dilute potassium hydroxide solution, to remove any free 2-acid, then with water, dried with calcium chloride, and the ether removed by evaporation. The residue was an oil, which did not solidify in an ordinary freezing mixture of ice and salt. As it was deemed unwise to attempt further purification by distillation, on account of the small amount in hand and the likelihood of some decomposition on heating,<sup>1</sup> the ester was saponified to the free acid by careful hydrolysis with alcoholic potassium hydroxide solution.<sup>2</sup>

After warming the ester on the water bath for a few minutes, a drop of the mixture was completely soluble in water, showing the total hydrolysis of the ester, and the solution was then largely diluted with water and acidified cold with dilute hydrochloric acid. A yellowish precipitate appeared, which was filtered out, washed, dried, washed with ligroin, to eliminate any 2-acid, again dried, and finally crystallized from very dilute alcohol.

As thus purified, it forms colorless, glassy scales, m.  $183^{\circ}$  (corr.); apparently insoluble in water or ligroin; slightly soluble in benzene, ether or chloroform; quite soluble in methyl or ethyl alcohol or in acetone.

Subs. 0.2632 g.: 14.0 cc. N at  $21^{\circ}$  and 748 mm. Calc. for  $C_{10}H_{12}.CO.NH.CH_2.COOH$ : N, 5.96. Found: N, 5.93.

**Repetition of the Method of Paterno and Fileti,<sup>3</sup> and of Paterno and Spica.<sup>4</sup>**—The anhydrous barium sulfonate of cymene was distilled dry with potassium cyanide, and the sodium sulfonate with potassium cyanide and with potassium ferrocyanide. In all cases, the results were most unsatisfactory, on account of the large amount of decomposition. The best results were secured by intimately mixing 10 g. anhydrous sodium sulfonate with an equal weight of potassium cyanide and heating the mixture as uniformly as possible, the temperature being raised gradually (5 minutes) until the thermometer registered  $240^{\circ}$  for the vapor distilling over, and then raising it to  $240-300^{\circ}$  for 10 minutes. Washed with sodium hydroxide solution, the crude liquid distillate amounted to 2.5 g.

20 g. of the crude nitrile so obtained were distilled with steam, the yellow, oily distillate collected with ether, dried with calcium chloride, and fractioned. The first fractions (below  $200^{\circ}$ ) were obviously cymene; from  $200$  to  $255^{\circ}$ , 5.5 g. of impure nitrile were collected as a pale yellow liquid. Kreyser<sup>5</sup> gives the b. p. of the nitrile as  $244-6^{\circ}$ . This impure

<sup>1</sup> *J. prakt. Chem.*, [2] **15**, 247 (1877).

<sup>2</sup> Compare *J. Chem. Soc.*, **79**, 397 (1901); *Ber.*, **31**, 3276 (1898).

<sup>3</sup> *Gazz. chim. ital.*, **5**, 30 (1875).

<sup>4</sup> *Ibid.*, **9**, 400 (1879).

<sup>5</sup> *Ber.*, **18**, 1714 (1885).

nitrile was saponified by boiling it with alcoholic potassium hydroxide solution under a reflux condenser. When the heating was continued for about 24 hours, the product was almost exclusively the amide; longer heating gave increasing amounts of the acid.

The amide so obtained crystallized from water in colorless, glassy needles, m.  $138-41^{\circ}$  (corr.), and this m. p. could not be altered either by further crystallization or by fractional crystallization. Paterno and Fileti give the m. p. of their amide as  $138-9^{\circ}$  (corr.). The above amide, m.  $138-41^{\circ}$ , mixed with some amide of the 2-acid prepared from the chloride of the 2-acid, showed a m. p. of  $139-44^{\circ}$  (uncorr.); but, when mixed with the amide of the 3-acid, melted at  $121-32^{\circ}$  (uncorr.).

A small amount of cymene 2-carboxylic acid recovered in the above saponification, when recrystallized from dilute alcohol, showed a m. p.  $69-71^{\circ}$ , and when mixed with some pure 2-acid, m.  $69-72^{\circ}$ . The acid obtained by Paterno and Spica, therefore, by fusing the amide with potassium hydroxide, or by heating it with concentrated hydrochloric acid at  $180^{\circ}$ , was manifestly an impure cymene 2-monocarboxylic acid.

## II. *p*-Cymene 3-Carboxylic Acid.

**3-Bromocymene** has been prepared by Von Gerichten<sup>1</sup> and by Fileti and Crosa<sup>2</sup> by the action of  $\text{PBr}_5$  upon thymol. The latter give the b. p. as  $232-3^{\circ}$  (in the vapor) at 740.9 mm. (reduced to  $0^{\circ}$ ). Kelbe and Koschnitzky<sup>3</sup> claimed to have obtained this bromocymene from what they believed to be the 3-bromocymene-6-sulfo acid; but Claus and Christ<sup>4</sup> were of opinion that the product obtained by these investigators was in reality the 2-bromocymene.

The 3-bromocymene used in the following experiments was made by the method of Fileti and Crosa from thymol and  $\text{PBr}_5$ , and our yields checked those of these investigators (60%). The purified material showed a b. p.  $231.2-233.2^{\circ}$  (corr.). It was found, further, that any increase in the amount of  $\text{PBr}_5$  above that given by Fileti and Crosa resulted in a decreased yield.

An effort was made to help the yield by the addition of fused zinc bromide to the reaction mixture, since Dehn and Davis<sup>5</sup> have shown that the presence of zinc chloride materially increases the amount of alkyl halide obtainable from the alcohol and phosphorus halide, but the results were unsatisfactory. The effect of fused zinc bromide upon tri-thymyl phosphate was also studied, in the hope that thereby the bromocymene might be secured directly from the phosphate which is a by-product in

<sup>1</sup> *Ber.*, 11, 1719 (1878).

<sup>2</sup> *Gazz. chim. ital.*, 16, 292 (1886).

<sup>3</sup> *Ber.*, 19, 1731 (1886).

<sup>4</sup> *Ibid.*, 19, 2165 (1886).

<sup>5</sup> *THIS JOURNAL*, 29, 1328 (1907).

the preparation of the bromocymene from thymol and  $\text{PBr}_5$ . It was expected that reaction might occur in the following sense:

The results were disappointing, for on distilling 60 g. of the tri-thymyl phosphate and 40 g. anhydrous zinc bromide (in intimate mixture) from a retort, but small amounts of the bromocymene were formed.

As has been pointed out already, in the foregoing, 3-bromocymene is also produced in the direct bromination of cymene.

**p-Cymene 3-Carboxylic Acid**,  $\text{C}_{10}\text{H}_{18}\text{COOH}$ , was prepared from 3-bromocymene, magnesium and  $\text{CO}_2$ , practically as described already for the isomeric 2-acid. In a typical experiment, 119 g. 3-bromocymene, 13.6 g. magnesium, and 300 cc. absolute ether, were treated for 16 hours with excess of  $\text{CO}_2$  under pressure, at a temperature below  $-5^\circ$ . The yield of crude acid was 55 g., or approximately 55% of the theoretical.

Purified by crystallization from dilute alcohol, this acid forms colorless, glassy needles, m.  $84^\circ$  (corr.); practically insoluble in cold water; difficultly soluble in hot water; more or less soluble in ligroin, benzene, xylene, methyl or ethyl alcohols, chloroform, carbon tetrachloride, acetone, carbon disulfide, dilute acetic acid or in ethyl acetate. It does not sublime, but distils at ordinary pressure with but little decomposition, b.  $285^\circ$  (corr.), and the distillate immediately solidifies. It volatilizes quite easily with steam, and when distilled with excess of soda lime gives cymene again. The unsatisfactory m. p. often found for this acid is due in most cases to moisture, rather than to the presence of other contaminants. For a sharp m. p., the acid must be dried for several days in a vacuum desiccator over calcium chloride, or heated for a short time at  $65\text{--}70^\circ$ .

Subs. 0.1800, 0.2034:  $\text{CO}_2$ , 0.4891, 0.5531;  $\text{H}_2\text{O}$ , 0.1264, 0.1455. Calc. for  $\text{C}_{10}\text{H}_{18}\text{O}_2$ : C, 74.16; H, 7.87. Found: C, 74.11, 74.16; H, 7.80, 7.95.

A cryoscopic molecular-weight determination in acetic acid gave the figures 172 and 175, the calculated figure being 178.

**Sodium Salt**,  $\text{NaA}$ .—The barium salt was dissolved in hot water, and a dilute solution of sodium carbonate added carefully as long as it caused a precipitate. The precipitated barium carbonate was then filtered out and the filtrate concentrated. As the salt is very soluble in water, this concentration must be carried practically to dryness. The salt is thus obtained as a white, pulverulent solid, which appears to deliquesce at  $10^\circ$ , but loses this water again at room temperature. It crystallizes without water of crystallization.

Anhydrous salt, 0.3100:  $\text{Na}_2\text{SO}_4$ , 0.1147. Calc. for  $\text{C}_{10}\text{H}_{18}\text{O}_2\text{Na}$ : Na, 11.50. Found: Na, 11.99.

**Potassium Salt**,  $\text{KA}$ .—A dilute solution of potassium hydroxide was treated with excess of the pure 3-acid, the excess of acid filtered out of the

cold solution, and the filtrate evaporated. The salt is very easily soluble in water, but carries no water of crystallization. It is a white powder.

Anhydrous salt, 0.3226:  $K_2SO_4$ , 0.1280. Calc. for  $C_{11}H_{13}O_2K$ : K, 18.09. Found: K, 17.82.

**Barium Salt**,  $BaA_2 \cdot 2H_2O$ .—Some of the free acid was suspended in hot water and digested for four or five hours with excess of barium carbonate at  $100^\circ$ . The acid dissolved gradually. The excess of barium carbonate was removed, and the filtrate concentrated to small volume, the salt then separating as a colorless solid, quite easily soluble in hot water.

Subs. 0.3412, heated to constant weight at  $110^\circ$ :  $H_2O$ , 0.0237. Calc. for  $(C_{11}H_{13}O_2)_2Ba \cdot 2H_2O$ :  $H_2O$ , 6.83. Found:  $H_2O$ , 6.94.

Anhydrous salt, 0.3146:  $BaSO_4$ , 0.1476. Calc. for  $(C_{11}H_{13}O_2)_2Ba$ : Ba, 27.9. Found: Ba, 27.6.

**Calcium Salt**,  $CaA_2 \cdot 2H_2O$ .—This salt was prepared in the same manner as the above Ba salt. It is much less soluble in water than the latter, and only slightly more soluble in hot than in cold water, separating in imperfect crystals.

Subs. 0.2882, dried to constant weight at  $110^\circ$ :  $H_2O$ , 0.0238. Calc. for  $(C_{11}H_{13}O_2)_2Ca \cdot 2H_2O$ :  $H_2O$ , 8.37. Found:  $H_2O$ , 8.26.

Anhydrous salt, 0.2644:  $CaSO_4$ , 0.0892. Calc. for  $(C_{11}H_{13}O_2)_2Ca$ : Ca, 10.15. Found: Ca, 9.96.

**Copper Salt**,  $CuA_2$ .—A copper acetate solution was added carefully to a hot aqueous solution of the calcium salt of the acid. The copper salt separated as an amorphous, light blue precipitate, which was filtered out, washed and dried. It is practically insoluble in water, but quite soluble in hot alcohol or in hot benzene, and crystallizes from alcohol in greenish blue microscopic needles, without water of crystallization.

**Silver Salt**,  $AgA$ .—This was prepared in the same manner as the silver salt of the 2-acid. It is colorless, apparently fairly stable in the light, and is somewhat soluble in water.

Subs. 0.2595, 0.2033: Ag, 0.0982;  $CO_2$ , 0.3487;  $H_2O$ , 0.0851. Calc. for  $C_{11}H_{13}O_2Ag$ : Ag, 37.87; C, 46.33; H, 4.56. Found: Ag, 37.84; C, 46.77; H, 4.65.

**Methyl Ester**,  $C_{10}H_{13} \cdot COOCH_3$ .—17 g. of the 3-acid were dissolved in a small excess of 10% potassium hydroxide solution, 23 g. of dimethyl sulfate added, and the mixture shaken vigorously for three hours. It was then heated for an hour on the water bath, to decompose any unchanged dimethyl sulfate, cooled, made slightly alkaline with potassium hydroxide and distilled with steam. The ester came over slowly as a colorless, heavy oil. It was collected with ether, the ethereal solution dried with calcium chloride, the ether distilled off and the residue fractionated at 13.5 mm. (reduced to  $0^\circ$ ), most of the ester (6.3 g.) then coming over at  $128-9^\circ$ , as a colorless liquid, with a characteristic pleasant odor.

Upon acidifying the residue from the steam distillation, 3.2 g. of the acid were recovered, its formation being probably referable to hydrolysis during the distillation with steam.

Subs. 0.1938:  $\text{CO}_2$ , 0.5324;  $\text{H}_2\text{O}$ , 0.1436. Calc. for  $\text{C}_{12}\text{H}_{16}\text{O}_2$ : C, 75.00; H, 8.33. Found: C, 74.92; H, 8.23.

**Ethyl Ester.**—15 g. of the acid were dissolved in a slight excess of potassium hydroxide solution, 25 g. (two mols) of diethyl sulfate added, the mixture shaken mechanically for three hours, and finally heated for an hour at  $100^\circ$ , to decompose the excess of diethyl sulfate. The ester separated as a pale yellowish oil. The mixture was made alkaline with KOH, the ester extracted with ether, the ether dried with calcium chloride, the solvent distilled off, and the residue fractioned under reduced pressure, collecting the fraction b.  $141-2^\circ$  at 13.5 mm. (corr.).

The product was a colorless oil, of pleasant odor, similar to that of the methyl ester but rather stronger. By acidifying the aqueous solution, after the ether extraction, some of the original acid was recovered.

Subs. 0.2059, 0.1413:  $\text{CO}_2$ , 0.5547, 0.3807;  $\text{H}_2\text{O}$ , 0.1596, 0.1100. Calc. for  $\text{C}_{12}\text{H}_{16}\text{O}_2$ : C, 75.72; H, 8.74. Found: C, 73.47, 73.48; H, 8.61, 8.65.

The product was, therefore, somewhat impure, the source of this contamination being possibly the commercial diethyl sulfate employed.

**Phenyl Ester.**—2.3 g. phenol (theory 2.1) were dissolved in 15 cc. pyridine, and 4.2 g. acid chloride added gradually with shaking and cooling. The solution soon turned red, and a white precipitate separated of pyridine hydrochloride. After standing overnight in the ice box, the mixture was poured into cold dilute sulfuric acid. An oil collected, which was washed thoroughly with water, to remove all pyridine, then with dilute caustic alkali, to remove any 3-acid, after which it was taken up in ether, the solution dried with calcium chloride, the ether evaporated and the residue fractioned at 22.5–24.5 mm. when it distilled at  $199-208^\circ$ . It remained a liquid, and all attempts to congeal it by freezing, or by leaving it in a desiccator over concentrated  $\text{H}_2\text{SO}_4$ , failed. The inference, therefore, is that this ester is either a liquid at ordinary temperatures or a low-melting solid.

The Acid Chloride was prepared in much the same way as the chloride of the 2-acid. The yield was 93% or better.

In the pure state, it is a colorless mobile liquid of penetrating odor, b.  $115-6^\circ$  at 9.2 mm., or  $128-9^\circ$  at 20.1 mm., and is slowly hydrolyzed by cold water.

**Acid Amide.**—3 g. of the acid chloride were dissolved in a small amount of anhydrous ether and a rapid current of dry ammonia past into the solution, cooling the vessel with a freezing mixture. An abundant white precipitate rapidly separated. The solution, saturated with ammonia, was allowed to stand for a short time and then filtered. Very little

amide remained in the ethereal filtrate. The original precipitate was washed thoroughly with water, to eliminate ammonium chloride, dried and crystallized from benzene. Yield before crystallization, 93%.

The pure amide crystallizes from benzene in radiating clusters of minute colorless, silky needles which mat together, and *m.* 137.5° (corr.). It is but slightly soluble in cold ligroin, benzene, ether or carbon tetrachloride; somewhat soluble in hot water; quite soluble in methyl or ethyl alcohol or in chloroform; and crystallizes well from either ligroin, benzene or carbon tetrachloride.

Subs. 0.2419: N, 16.82 cc. at 21° and 753 mm. Calc. for  $C_{11}H_{18}ON$ : N, 7.91. Found: N, 7.81.

**Acid Anilide.**—A dry ether solution of 3 g. of the acid chloride was added gradually, with shaking and cooling, to a dry ether solution of 6 g. aniline (4 mols.). A colorless precipitate appeared, and heat was liberated in the reaction. After standing overnight, the mixture was filtered and anilide was found both in the original precipitate and in the ethereal filtrate. From the latter, it was recovered by simple evaporation of the solvent; from the former, by washing with water, to remove aniline salt. The two lots thus secured were united, washed with a little dilute hydrochloric acid, to eliminate final traces of aniline, then with water, and dried. Yield, 74%.

The anilide is quite soluble in methyl alcohol, ethyl alcohol, ether, benzene, or chloroform, and but slightly soluble in water. It can be crystallized from ligroin, carbon tetrachloride or dilute alcohol. From the latter, it separates in beautiful colorless, silky needles, *m.* 151° (corr.).

Subs. 0.3350, 0.2722: N, 17.1 cc. at 19° and 751 mm.; 13.1 cc. at 18.5° and 762 mm. Calc. for  $C_{17}H_{19}ON$ : N, 5.53. Found: N, 5.78, 5.53.

**Sym.-3,3'-Dimethyl-6,6'-diisopropyl Dibenzoylhydrazine**,  $C_{10}H_{13}.CO.NH.NH.CO.C_{10}H_{13}$ .—The procedure for the synthesis of this hydrazine was the same as in the case of the analogous derivative of the 2-acid, using 10 g. of the acid chloride and 11 g. of 50% aqueous hydrazine hydrate solution. The crude product was washed with water, to remove hydrazine salt, and then with dilute sodium hydroxide solution, to eliminate any 3-acid. Acidification of the alkaline washings showed that practically none of the acid chloride had been hydrolyzed. Yield of crude diacyl hydrazine, 93%.

The pure compound crystallized in fine, colorless, silky needles, from alcohol, and *m.* 213.5° (corr.). It is very slightly soluble in ether, slightly soluble in chloroform or acetic acid, and moderately soluble in methyl alcohol, ethyl alcohol, benzene or acetone.

Subs. 0.1645: N, 11.90 cc. at 21° and 753 mm. Calc. for  $C_{22}H_{28}O_2N_2$ : N, 7.95. Found: N, 8.12.

$\alpha,\alpha'$ -3,3'-Di-*p*-cymyl-[*bb*<sub>1</sub>]-furodiazole was obtained by heating 2.5

g. of the above diacyl hydrazine at  $200^{\circ}$  or higher for about two hours, cooling, and extracting with benzene. The insoluble residue, 0.5 g. in amount, proved to be unchanged diacyl hydrazine. The benzene solution was boiled with boneblack, filtered, and the benzene evaporated, leaving behind 1.3 g. of the furodiazole sought.

Crystallized from methyl alcohol, this diazole forms long, colorless, silky needles, much like the corresponding derivative of the 2-acid, and m.  $132.5^{\circ}$  (corr.). It is insoluble in water, slightly soluble in methyl alcohol or ethyl alcohol; quite soluble in benzene, benzine, chloroform, ether or acetone.

Subs. 0.1739: N, 12.9 cc. at  $20.5^{\circ}$  and 750.7 mm: Calc. for  $C_{22}H_{20}ON_2$ : N, 8.38. Found: N, 8.32.

An attempt to obtain the hydrazide chloride by the action of  $PCl_5$  upon the diacyl hydrazine, as described by Stollé<sup>1</sup> gave a final product composed of the furodiazole mixed with the hydrazide chloride sought, but the latter is apparently so unstable and reactive that our efforts to separate it in the pure state were fruitless. That it was present in the mixture was demonstrated by the amount of halogen found, the liberation of HCl during the attempted purification, and the production therefrom of the pyrrodiazole noted beyond.

The action of  $P_2S_5$  upon the diacyl hydrazine likewise yielded a mixture composed largely of the furodiazole, and from which no pure thiodiazole could be isolated. The difficulty in all these reactions is the ease with which the diacyl hydrazine loses water and goes over to the furodiazole condition.

**$\alpha, \alpha'-3,3'$ -Di-*p*-cymyl-N-phenyl-[*bb*<sub>1</sub>]-pyrrodiazole,**

—6 g. of the mixture of hydrazide chloride

and furodiazole obtained from the diacyl hydrazine and  $PCl_5$  by the method noted above, were warmed gradually to  $170^{\circ}$  and kept at that temperature (thermometer in melt) for half an hour. The mass fused slowly and quietly and on cooling formed a bluish green semisolid melt. It was washed thoroughly with dilute hydrochloric acid, to remove aniline, and then with ether, to remove the furodiazole. The residue was crystallized repeatedly from dilute alcohol, and the pyrrodiazole thus obtained in small compact, colorless, glassy crystals, m.  $182.5^{\circ}$  (corr.).

<sup>1</sup> *J. prakt. Chem.*, [2] 73, 288 (1906); 74, 1, 13 (1906); see also Thoma, *Inaug. Diss.*, Heidelberg, 1904.

It is practically insoluble in water or benzene, moderately soluble in ether, and quite soluble in benzene, methyl alcohol, ethyl alcohol, chloroform, carbon tetrachloride or acetone.

Subs. 0.1360: N, 12.7 cc. at 22° and 751 mm. Calc. for  $C_{22}H_{21}N_3$ : N, 10.27. Found: N, 10.45.

From the ether washings of the crude product, there were isolated both the furodiazole (m. 132.5°, corr.) and the above pyrrodiazole (m. 182.5°, corr.).

**3-Methyl-6-isopropyl Hippuric Acid**,  $CH_3(C_2H_7)C_6H_3.CO.NH.CH_2-COOH$ .—2 g. of the acid chloride were added to a concentrated aqueous solution of 2 g. glycine, then a little dilute sodium hydroxide solution, and the mixture shaken mechanically, testing from time to time and adding more alkali as needed to maintain a feebly alkaline reaction. In two hours the acid chloride had essentially all dissolved and the mixture was acidified cold with dilute hydrochloric acid. The white precipitate which separated was removed, washed with ligroin, to rid it of any 3-acid, and crystallized by dissolving it in a small quantity of alcohol, then pouring in several volumes of boiling water and allowing to stand. The colorless pearly scales resulting were thoroughly washed with cold ligroin, and then m. 205.5° (corr.).

As thus purified, this hippuric acid derivative is soluble in methyl alcohol, ethyl alcohol or acetone; much less soluble in chloroform or ether; still less in benzene or carbon tetrachloride, and practically insoluble in water or ligroin.

Subs. 0.1743: N, 9.45 cc. at 22° and 746.5 mm. Calc. for  $C_{18}H_{17}O_2N$ : N, 5.96. Found: N, 6.00.

The use of heat to hasten this reaction is objectionable, as it causes too much hydrolysis of the acid chloride with consequent falling off in the yield of hippuric derivative.

**Oxidation of Cymene 3-Carboxylic Acid**.—Preliminary experiments indicated the formation of the following acids on oxidation of cymene 3-carboxylic acid:

By oxidation with dilute (1 : 1) nitric acid, an acid was obtained, m. 218–24°, believed to be trimellitic acid, the m. p. of which is variously, stated in the literature from 217 to 225°.

With alkaline potassium permanganate, an acid resulted, m.  $233-5^{\circ}$  (uncorr.), apparently isopropyl *m*-phthalic acid (m.  $236^{\circ}$ ) and, by further oxidation, an acid, m.  $195-8^{\circ}$ , which gave an impure ethyl ester, m.  $102-5^{\circ}$ . The latter is, therefore, probably the dimethylphthalide *m*-carboxylic acid, which m.  $205-6^{\circ}$ , and its ethyl ester at  $105-6^{\circ}$ .

Unfortunately, the reactions were not carried out with enough material to adequately purify these oxidation products and more definitely establish their identity, but it is hoped to complete this part of the work at a later date.

**Reduction of Cymene 3-Carboxylic Acid.**—A solution of the acid in glacial acetic acid was mixed with a solution of colloidal platinum, and the resulting homogeneous solution shaken mechanically for 20 hours while it was subjected to treatment with hydrogen at 13 lbs. pressure. No reduction occurred, the original acid being recovered unchanged. Experiments on the reduction of an amyl alcohol solution of the acid by metallic sodium are under way and will be reported later.

#### Summary of Results.

1. The syntheses of *p*-cymene 2-carboxylic acid and of *p*-cymene 3-carboxylic acid, have been accomplished from the corresponding bromo cymenes, and numerous derivatives of these acids prepared and studied.

2. The statements in the literature concerning cymene 2-carboxylic acid and its salts have been tested and corrected. The following hitherto unknown derivatives have been prepared: methyl ester, ethyl ester, acid chloride, acid anilide, diacyl hydrazine, the furodiazole condensation product from the latter, the cymyl hippuric acid and its ethyl ester.

3. Cymene 3-carboxylic acid is entirely new. In addition to the free acid, the following derivatives have been synthesized and examined: Na, K, Ca, Ba, Cu and Ag salts, methyl ester, ethyl ester, phenyl ester, acid chloride, acid amide, acid anilide, diacyl hydrazine, the furo- and *N*-phenyl pyrrodiazole condensation products from the latter, and the cymyl hippuric acid.

4. The bromination product of cymene has been shown to be a mixture of 2- and 3-bromo derivatives, and not a pure 2-bromo derivative as hitherto assumed.

### THE HYDROLYSIS OF CHLOROPENTANES AS AFFECTED BY HIGH PRESSURE: SYNTHETIC FUSEL OIL.

By HARRY ESSEX, HAROLD HIBBERT AND BENJAMIN T. BROOKS.

Received May 6, 1916.

The recent work of Meyer and Bergius<sup>1</sup> on the conversion of chlorobenzene and chloronaphthalene into phenol and  $\alpha$ -naphthol, respectively,

<sup>1</sup> *Ber.*, 47, 3155 (1914).

by heating the chlorides with aqueous alkalis at about  $300^{\circ}$  and 1500 pounds<sup>1</sup> pressure, showed that the yields were increased by pressure and to a very striking degree. We have employed similar conditions and also much higher pressures with chloropentanes with the object of studying their conversion into the amyl alcohols. Obviously the two cases show several marked points of difference. Benzene dissociates on heating to about  $550^{\circ}$ , giving hydrogen and diphenyl,<sup>1</sup>

The temperature at which the dissociation of chlorobenzene first becomes appreciable must be somewhat lower than this, although Meyer and Bergius heated chlorobenzene with water vapor at atmospheric pressure at  $500^{\circ}$  without any noticeable reaction.

In the presence of considerable excess of 15% NaOH solution at  $300^{\circ}$ , Meyer and Bergius obtained first diphenyl ether and finally, after longer heating, nearly theoretical yields of phenol. Dilute alkalis, lime, sodium carbonate and borax solutions had very little effect on chlorobenzene under the same conditions of pressure and temperature. Our findings on the behavior of chloropentane differ very markedly from their results. With the alkyl chloride, we obtained practically the same yields of alcohol with sodium carbonate as with caustic soda and even larger yields with sodium acetate than with sodium carbonate under conditions otherwise substantially the same. The amount of diamyl ether formed was usually very small, never exceeding 8%. When glacial acetic acid is employed as a solvent, the relatively more stable amylacetate is obtained in much larger yields and at much lower pressures.

These results appear to be explained in a very satisfactory manner by Nef's<sup>2</sup> theory of the manner in which the alkyl halides dissociate and then react with other substances by addition.

<sup>1</sup> Cf. Engler, *Das Erdöl*, Vol. I, 576.

<sup>2</sup> THIS JOURNAL, 26, 1570 (1904); *Ann.*, 309, 126; 318, 1.

The relative ease with which some of the compounds of the ethane series, the hydrocarbon, alkyl chloride, alcohol, ether and sodium alcoholate appreciably decompose is shown in the following:<sup>1</sup>

Substance.	Temperature.
Ethane $\text{CH}_3\text{CH}$ 	800°
Ethyl alcohol $\text{CH}_3\text{CH}$ 	650°
Ethyl chloride $\text{CH}_3\text{CH}$ 	510-530°
Ethyl ether $\text{CH}_3\text{CH}$ 	550°
Sodium ethylate $\text{CH}_3\text{CH}$ 	250°
Ethyl acetate $\text{CH}_3\text{CH}$ 	"low red heat" <sup>2</sup>

Comparative data for the corresponding compounds of the *n*-pentane series are lacking. The relative stability of the primary derivatives of *n*-pentane is undoubtedly of the same order, with respect to one another, as in the ethane series. The same probably holds in the series of secondary derivatives. The chloropentanes employed in this work were prepared from petroleum pentane, as herein described, and consisted of the 1, 2 and 3 monochloro derivatives.

The effect of caustic alkali in producing increased yields of amylene, as compared with sodium carbonate, borax and sodium acetate, finds a ready explanation in the low dissociation temperature of the sodium alcoholate. This would have the effect of increasing the concentration of the dissociated methene, which has the result of increasing the amount of olefine formed,<sup>3</sup> as is expressed by Equations 3 and 4. To produce

<sup>1</sup> Nef, *Loc. cit.*

<sup>2</sup> Oppenheim and Precht, *Ber.*, 9, 325 (1876).

<sup>3</sup> Nef, *Ann.*, 318, 1 (1901) has shown that when isoamyl chloride, bromide and iodide are heated with alcoholic sodium ethylate, the chloride gives the greatest yield of isoamyl ethyl ether and the iodide the largest yield of amylene, which he explains by assuming that the rate of the addition of alcohol to the dissociated methene is not sufficient to combine with the latter as fast as formed, resulting in its partial rearrangement to amylene.

large yields of amyl alcohol in the presence of caustic alkali, the temperature should not exceed that at which the dissociation of sodium amylate takes place to a sensible degree. But this temperature is so much lower than the temperature at which the dissociation of the chloride becomes appreciable that the formation of alcohol or alcoholate is extremely slow. Higher yields of alcohol are therefore obtained when employing temperatures sufficient to dissociate the chloride at a fairly rapid rate,  $215^{\circ}$ , and solutions of a weak base or the alkali salt of a very weak acid, so that the HCl split off is taken up. It should be pointed out that, excepting the olefine, the alcohol is the most stable substance in the system.

In the presence of glacial acetic acid much higher yields of alkyl acetate than of alcohol are obtained when water is employed as the solvent, the conditions of temperature and pressure being the same in the two cases.<sup>1</sup>

This may be due to the fact that glacial acetic acid is more highly dissociated than water. It would then be expected that dissociated methene of a given concentration would react more rapidly with acetic acid than with water, or, in other words, a lower temperature (lower concentration)

of  $\begin{array}{c} \text{R} \\ \diagup \\ \text{C} \\ \diagdown \\ \text{R}_1 \end{array}$  should suffice to produce a given yield of product, *i. e.*, acetate. Higher yields are obtained when anhydrous sodium acetate is added to the mixture than when glacial acetic acid alone is employed, the function of the sodium acetate apparently being to take up the hydrogen chloride with the formation of sodium chloride and the liberation of acetic acid.

It now remains to consider the effect of pressure on the two systems chloropentane and water; and chloropentane, water and alkali. It is obvious that in the case of chloropentane alone the effect of increased pressure will be to prevent the dissociation as indicated in Equation 1. Increased pressure should effect the dissociation of the alcohol, Equation 2, in the same direction. As has been noted above, the addition of caustic alkali causes increased formation of olefine at the expense of alcohol, which we interpret as being brought about by the effect of caustic alkali in increasing the concentration of  $\begin{array}{c} \text{R} \\ \diagup \\ \text{C} \\ \diagdown \\ \text{R}_1 \end{array}$ . Increase of pressure

should, therefore, tend to confine the reactions which take place to

<sup>1</sup> The data on these experiments are reserved for later publication.

those expressed by (1) and (2). If the volume change of Equation 2 is greater than that of Equation 1, then increase in pressure should cause the alcohol to become relatively more stable with respect to the chloride; in other words, the difference of temperature between the "decomposition temperature" of amyl alcohol and amyl chloride becomes greater at high pressures. Probably a similar difference in stability would be found in the case of ethyl chloride and ethyl alcohol at high pressure.

We have found that heating monochloropentane with water vapor at atmospheric pressure until decomposition becomes appreciable leads to the formation of amylene almost exclusively. In the same way, Meyer and Bergius<sup>1</sup> found that by heating chlorobenzene and water vapor at atmospheric pressure to temperatures at which decomposition could be noted, namely, nearly 600°, only 10% of phenol was formed after "several hours" heating in an apparatus arranged for circulating and repeatedly heating the vapors.

### Experimental.

The pressure bomb employed was very simple in construction, a piece of seamless steel tubing 30 inches long, internal diameter 2.5 inches and 0.75 inch thickness of wall. The open ends were carefully machined and threaded so as to be closed by conical plugs forced in to place by heavy forged steel screw plugs. The conical plugs, sealing the interior chamber, were kept centered during the closing operation by the centering pins passing through the screw plugs, and were tapered a few degrees less than the seat machined in the tube, as shown in the sketch. A valve was provided for escape of gas, such as CO<sub>2</sub>, produced in some of the reactions. The temperature in the bomb was read by a thermocouple placed in the thermometer-well shown and the pressure indicated on an hydraulic gage, reading to ten thousand pounds per square inch. The heating was accomplished electrically by means of a simply constructed nichrome wire resistance furnace and it was found possible to control the temperature in the bomb to about  $\pm 2^\circ$  of the desired point. In order to attain pressures higher than were given by water and the reaction products, ether was added in some cases, and in many cases the bomb was filled completely with the liquid mixture.

<sup>1</sup> Loc. cit.

Meyer and Bergius mention the use of cuprous chloride as a catalyst accelerating the reaction in the case of chlorobenzene. In our work with amyl chlorides, we were unable to detect any effect in the rate or character of the reaction which could be attributed to this substance. Basic lead carbonate was also tried, but without result.

In working up the resulting reaction mixtures, the liquid layer was separated, washed with water, dried with anhydrous sodium sulfate and fractionated. The fusel oil distils over in the fraction boiling above  $115^{\circ}$ , but, since appreciable quantities distil with the fraction-boiling point  $100-115^{\circ}$ , this fraction was acetylated and refractionated. The acetylated product obtained, boiling above  $115^{\circ}$ , was then calculated back to amyl alcohol. The unchanged chlorides, contained in the fusel oil fraction, were found by analyzing for chlorine by the method of Drogin and Rosanoff<sup>1</sup> and making the necessary correction. That the polymerization of the amylene, formed as a by-product, to diamylene occurs to slight extent under the conditions prevailing in these experiments is indicated by the following distillation results:

#### FRACTIONAL DISTILLATION OF ALCOHOL PORTION.

Distillation temperatures.	Quantity per cent.
$115-125^{\circ}$ .....	22.8
$125-140^{\circ}$ .....	53.1
$140-150^{\circ}$ .....	2.7
$150-170^{\circ}$ .....	11.7 <sup>2</sup>
$170-190^{\circ}$ .....	5.5
Residue and loss .....	4.2

That the large yields, generally obtained in the experiments in which ether was added to the reaction mixture, are due primarily to the resulting higher pressure and not to any catalytic or solvent action is indicated by the equally large yields in those experiments in which the conditions were substantially the same, but containing no ether in the reaction mixture, and also by the fact that, comparing a series in which ether was introduced, those carried out at the higher pressures gave much higher yields of alcohol, other factors remaining the same.

## BRAIN CEPHALIN. II. FATTY ACIDS.

By C. G. MACARTHUR AND L. V. BURTON.

Received April 1, 1916.

As has been stated in the previous article of this series,<sup>1</sup> there is some uncertainty as to what fatty acids are present in the cephalin molecule and considerable uncertainty as to the amounts of each.

**Preparation.**—In this work preparations have been made in several ways, some old, some new, to see whether there are consistent differences in the molecule depending on the method of preparation.

Cephalins (1), (2), (3) and (4) were prepared and purified as described in the previous paper. Another preparation, purified like cephalin (4), was further purified by dissolving in chloroform and precipitating with twice the solution's volume of absolute alcohol. The object of this treatment was to remove any trace of sphingomyelin that might still contaminate the product. The desiccated material was then emulsified in water and precipitated by an equal volume of acetone. The precipitate was further washed with acetone, placed in a vacuum desiccator and dried, then taken up in ether, centrifuged, and precipitated by acetone and dried. This will be referred to as cephalin (8). It is a light yellow powdery product, similar in appearance to cephalin (4).

**Percentage of Total Fatty Acids in Cephalin.**—To determine the percentage of total fatty acids in cephalin, one gram of the cephalin was hydrolyzed for 20 hours in a 1% hydrochloric acid solution. The fatty acid residue, after filtration, was dissolved in ether, filtered, and carefully evaporated to dryness in a weighed dish. It was dried over sulfuric acid till constant weight was obtained. By this method cephalin (1) (HCl purified) gave 0.670 g. of fatty acids. One gram of cephalin (4) gave 0.652 g. The fatty acids from another sample of cephalin (1) weighed 0.66 g. From this data it seems that 66% of cephalin is in the form of fatty acids. It is likely that these values are slightly high because there is a small amount of an unhydrolyzable substance that would be included in the total fatty acids.

### Quantitative Study.

Four grams (usually) of the cephalin were dissolved in 200 cc. of a 2% water potassium hydroxide solution. This was boiled for 20 hours under a reflux condenser, cooled and acidified with acetic acid. The fatty acids were filtered rapidly, washed three times with distilled water, then dissolved in dilute potassium hydroxide. The solution was now neutralized with acetic acid and an equal volume (about 150 cc.) of a 5% lead acetate solution added. The lead soaps were filtered through a

<sup>1</sup> MacArthur, *THIS JOURNAL*, 36, 2397 (1914).

hardened filter, washed three times, and dried with filter paper and then in a vacuum desiccator. The comparatively dry soaps were carefully placed in a flask and refluxed with about 150 cc. of freshly distilled ether for several hours until all the particles were finely divided. The contents of the flask were cooled and either filtered or centrifuged and washed with small amounts of ether. In some experiments better results were obtained by allowing this solution to stand a few hours in a tall cylinder and then siphoning off the clear solution. The residue was washed three times.

The saturated insoluble lead soaps were decomposed either by passing  $\text{H}_2\text{S}$  through the hot benzene solution, or by refluxing the lead soap with an ether and hydrochloric acid solution in the usual manner. Several repetitions of this procedure were necessary. The free acids were evaporated to dryness and weighed. This gave the total saturated acids. The product was then recrystallized several times from alcohol and acetone, and was ready for melting point and molecular-weight determinations and derivatives.

The unsaturated lead soaps were decomposed by shaking the ether solution with several portions of a dilute  $\text{HCl}$  solution. The ether solution was then washed with water, dried with anhydrous sodium sulfate, and filtered into a flask.

The solution of the unsaturated acids was cooled in ice water, and bromine added in small portions till an excess was present. They were allowed to stand overnight in ice bath in the ice box, then placed in a corked weighed centrifuge tube and the ether-insoluble bromine derivative centrifuged out. It was washed with ether several times, dried and weighed. From a bromine determination on this compound the amount of fatty acid in it could be calculated. The bromine determination also helped to identify the acid.

The ether solution of the ether-soluble bromine derivatives was placed in a separatory funnel and an excess of sodium thiosulfate added. The funnel was thoroughly shaken, allowed to stand, and then the water layer was drawn off. The ether was again treated with sodium thiosulfate. Finally it was washed with several portions of water, dehydrated with anhydrous sodium sulfate, filtered into a weighed beaker and carefully evaporated to dryness. The weight gave the amount of the ether-soluble bromine derivatives.

To separate these the mixture was extracted at room temperature several times with small portions of petroleum ether (b. p.  $30-50^\circ$ ). A white insoluble bromide remained. The petroleum ether solution was evaporated carefully to dryness and the residue again treated with small amounts of petroleum ether. A small portion remained undissolved. These two residues were united, dried and weighed. They represent the

petroleum-ether-insoluble bromine derivative. From the bromine determination the amount of free fatty acid was determined. This bromine value and the melting point were used to give an idea of the identity of the compound.

The petroleum ether solution was evaporated to dryness in a weighed beaker. This gave the petroleum-ether-soluble bromine derivative. As a rule this weighed residue was dissolved in acetone. There was a small amount of an acetone-insoluble saturated compound containing 1.3% nitrogen left, probably not fatty acid. The solution was evaporated and weighed. This gave the true weight of the liquid dibromide. From the amount of bromine in it the amount of the fatty acid could be calculated.

By the above procedure the following data were obtained:

TABLE I.

2 g. sheep cephalin (8). Calculated weight of acids = 1.32 g.

	Wt. of bromide.	Wt. of acid.	% of total acids.
Stearic acid.....	..	0.43	32.6
Oleic acid.....	1.14	0.73	55.4
Cephalinic acid.....	0.24	0.09	7.0
Clupanodonic acid.....	0.17	0.05	3.9
		<hr/>	<hr/>
		1.30	98.9

6 g. sheep cephalin (4). Calculated weight of acids = 3.96 g.

Stearic acid.....	..	1.21	30.6
Oleic acid.....	3.41	2.18	55.5
Cephalinic acid.....	0.64	0.26	6.5
Clupanodonic acid.....	0.49	0.16	4.0
		<hr/>	<hr/>
		3.73	96.6

3 g. beef cephalin (4). Calculated weight of acids = 1.98 g.

Stearic acid.....	..	0.58	29.3
Oleic acid.....	1.60	1.05	53.0
Cephalinic acid.....	0.36	0.15	7.5
Clupanodonic acid.....	0.21	0.07	3.5
		<hr/>	<hr/>
		1.85	93.3

In a few analyses the hydrolysis of the cephalin and the solution of the fatty acids in ether were carried out as above described. Instead of separating the saturated from the unsaturated acids, however, the ether solution was brominated and separated as before. The saturated acids will be in with the oleic bromide. The two were weighed together, then from a bromine determination on a fraction of this mixture the amount of oleic bromide and oleic acid could be calculated. The difference between the weight of oleic bromide and that of the mixture was assumed to be stearic acid. From the following data it will be noticed that the agreement is rather close with that of the lead method:

TABLE II.

3 g. sheep cephalin (4). Calculated weight of acids = 1.98 g.

	Wt. of bromide.	Wt. of acid.	% of total acids.
Stearic acid.....	..	0.55	27.8
Oleic acid.....	1.75	1.12	56.6
Cephalinic acid.....	0.45	0.18	9.0
Clupanodonic acid.....	0.23	0.07	3.5
		<hr/>	<hr/>
		1.92	96.9

**Discussion of Quantitative Experiments.**—A consideration of the data will show that there is no definite relationship between the amounts of the various acids in cephalin. Stearic acid comprises somewhat more than one-fourth of the total fatty acids. According to the generally accepted formula of cephalin, one-half of the cephalin would be present as stearic acid. Oleic acid constitutes about one-half of the total acids. Approximately one-tenth is cephalinic acid, and one-twentieth clupanodonic. It might be thought that one nitrogen constituent was present with each acid, thus giving a mixture of stearyl cephalin, oleyl cephalin, etc. There does not seem to be enough agreement, however, between the amounts of the nitrogenous compounds and the acids to warrant this assumption.

To explain the presence of these acids in such different amounts, it is best to assume that some of the cephalin molecules may have oleic and cephalinic acids, and still others stearic and cephalinic, etc. It is well known that ordinary fats are often thus mixed. It is reasonable, then, to suppose that a highly labile compound like cephalin may have varying fatty acids on any particular molecule. They may even be changing from molecule to molecule in the cephalin mixture.

It is exceedingly difficult to purify cephalin. It is next to impossible to separate the constituents of the mixture, even though some of the supposed cephalin molecules have such different acids as clupanodonic and stearic in them. Because of these facts one may think of cephalin as made up of several constituents more closely associated than a mixture but less so than a simple compound. It may be this power of forming comparatively firm association compounds that partially explains its peculiar importance in brain cell metabolism.

#### Identification of the Fatty Acids.

To obtain the individual fatty acids or their derivatives for identification, the same procedure was used in most cases as for the quantitative data. For a few experiments, in order to obtain larger amounts of the ether-insoluble and petroleum-ether-insoluble derivatives, 8 g. of the cephalin were hydrolyzed as described and all the free fatty acids dissolved in ether, then brominated and separated according to the above method. In this way the saturated acids went into the ether-soluble bromide fraction, and so did not interfere with the preparations sought.

**Stearic Acid.**—The somewhat impure saturated acid obtained from sheep cephalin (4) by the quantitative procedure described above gave a molecular weight of 289, a sample of sheep cephalin (1) gave 290.

(4) 0.1096 g. acid.....	3.7 cc. 0.1 <i>N</i> alk.	289 m. w.
(1) 0.2285 g. acid.....	7.8 cc. 0.1 <i>N</i> alk.	290 m. w.

These results were obtained by the usual procedure, dissolving the acid in a definite amount of alcohol and titrating with 0.1 *N* alkali. The number of cc. used in a control on an equal volume of alcohol was subtracted from the fatty acid value.

These impure samples were crystallized twice from alcohol and twice from acetone. The molecular weights then were 284.5 and 284.

(4) 0.2310 g. acid.....	7.95 cc. 0.1 <i>N</i> alk.	284.5 m. w.
(1) 0.2080 g. acid.....	7.15 cc. 0.1 <i>N</i> alk.	284.0 m. w.

This pure acid melted at 69°. Several other samples purified by crystallization from alcohol and acetone gave melting points varying from 68.8° to 69.2°.

The ethyl ester prepared in the usual way had a melting point of 33.4°.

Because the molecular weight of stearic acid is 284, its melting point is 69°, and ethyl stearate melts at 33.5° it may be concluded that stearic acid is the only saturated acid in cephalin in appreciable amounts. It was not determined what impurity present caused the high molecular weight of the impure stearic acid.

**Oleic Acid.**—The ether-soluble bromide fraction, after removal of the nitrogenous impurity by the latter's insolubility in acetone, was evaporated to dryness, dried over sulfuric acid and a bromine determination made on the heavy yellowish oil in the following way:

About 0.3 g. of the bromine derivative was carefully weighed into a nickel crucible. Ten grams of sodium hydroxide and 3 g. of potassium nitrate and a few drops of water were added. The crucible was covered and carefully heated to avoid spattering. Gradually the flame was raised till a melt was obtained. The heating was continued till the liquid was perfectly clear. It was allowed to cool partially, then was dissolved in water and made slightly acid with nitric acid. One cc. of 10% ferric ammonium sulfate was added and the solution titrated with 0.1 *N* silver nitrate and ammonium thiocyanide.

A few typical determinations out of many on the ether-soluble bromine fraction are given below:

	Bromine.
Sheep cephalin (8) 0.3000 g. bromine compound.....	36.5%
Sheep cephalin (4) 0.3891 g. bromine compound.....	37.0%
Sheep cephalin (1) 0.3353 g. bromine compound.....	34.5%
Beef cephalin (4) 0.3047 g. bromine compound.....	34.5%

The lowness of a few of the values can easily be accounted for by supposing that a small amount of stearic acid was present. That would

be the case if the lead separation had not been complete, and of that it is difficult to be certain.

In order to be sure that this method of determining the bromine content of a fatty acid derivative was entirely correct, the amount of bromine in pure dibromostearic acid, tetrabromostearic acid and hexabromostearic acid was found.

	G.	Obtained. Br.	Theoretical. Br.
Pure dibromostearic acid.....	0.2941	35.9%	36.2%
Pure tetrabromostearic acid.....	0.2134	53.2%	53.3%
Pure hexabromostearic acid.....	0.1070	62.8%	63.3%

It will be noticed that these values agree as well as could be expected with the theoretical bromine values.

The identity of the oleic acid was more firmly established by oxidizing a mixture of the fatty acids of cephalin in the usual way with a permanganate solution. A hydroxy derivative was found that had the properties of dihydroxy stearic acid. It was insoluble in water, somewhat soluble in ether, and readily soluble in hot alcohol.

**Cephalinic Acid.**—The petroleum-ether-insoluble fraction was purified by dissolving it in ether and filtering to remove any hexa or octa bromine derivatives. The ether solution was evaporated to dryness and the residue recrystallized from petroleum ether.

From the work done on this bromine derivative it is difficult to say what the formula of the compound really is. The bromine values found can be interpreted in several ways.

	Br.
Sheep cephalin (8) 0.2214 g. bromine compound.....	61.4%
Sheep cephalin (4) 0.2112 g. bromine compound.....	59.8%
Sheep cephalin (4) 0.2115 g. bromine compound.....	60.5%
Beef cephalin (4) 0.1178 g. bromine compound.....	59.0%

Though the bromine derivative from the best samples of cephalin gave about 60% of bromine, a few were as low as 56%. Probably the best way to explain low values in the petroleum-ether-insoluble fraction is by reasoning that any of the partially oxidized fatty acids, when brominated and separated as above described, would go into this fraction. It is extremely difficult to be sure that the product has been freed from such oxybromo acids. They would lower the bromine value. It is almost impossible, even with the precautions adopted against oxidation in this investigation, to say with certainty that no unsaturated bonds in the fatty acids had been saturated with oxygen. The principle evidence of oxidation in the cephalin was a darkening in color. Cephalin (4) and (8) were about white; a faint yellowish color was evident when a compact mass was observed. The amount of oxidation was very small, at most.

It is probably not a hexabromobehenic or lignoceric acid, because one

would expect these derivatives to have melting points about  $180^{\circ}$  whereas the best samples of cephalinic bromide melted at about  $120^{\circ}$ . The bromides of the higher acids would undoubtedly be even less soluble in ether than hexabromostearic acid, but the bromide of cephalinic acid is soluble in ether, though not so readily soluble as the tetrabromostearic acid. Besides, the melting point is too high for the tetrabromo compound. There seems to be no tendency, even at high temperatures, to form the soluble linolic bromide. The appearance of cephalinic bromide is also different from linolic bromide. The former crystallizes out of ether, slowly but continuously as the ether evaporates, in rather heavy plates, while the latter does not crystallize till the ether solution is concentrated, and then it separates as needles or as a semisolid mass containing the liquid as well as solid tetrabromide. The characteristics of the cephalinic bromide agree best with Thudicum's<sup>1</sup> data on the barium salt. From his results cephalinic acid would be probably an hydroxypalmitic or stearic acid with four unsaturated bonds in it. The data in this paper agree fairly well with a tetrabromo hydroxypalmitic acid.

#### Clupanodonic Acid.

The ether-insoluble bromine fraction gave bromine values ranging from 67% to 69.4%. Several analyses on the best cephalin preparations follow:

	Br.
Beef cephalin (4) 0.0827 g. bromine compound.....	67.7%
Sheep cephalin (4) 0.2144 g. bromine compound.....	69.4%
Sheep cephalin (8) 0.1967 g. bromine compound.....	68.8%
Sheep cephalin (4) 0.2260 g. bromine compound.....	68.7%

The theoretical percentage of bromine in octobromostearic acid is 69.6. The above values agree as well as one could expect, considering the possibilities of slight oxidation during the preparation and hydrolysis of the cephalin. However, the difference in amount of bromine in  $C_{18}H_{28}O_2Br_8$  and  $C_{20}H_{32}O_2Br_8$  is but 2%. There is some evidence for believing that the latter compound is one of the bromination products of liver lecithin. It is entirely possible, then, that the ether-insoluble bromo compound is not a derivative of clupanodonic acid but of the next higher homolog. The values more nearly agree with clupanodonic acid, however.

This difficulty was not solved by melting-point determinations on the bromo compound. When heated rather rapidly it darkens at  $220^{\circ}$  but does not melt. Because of the uncertainty of this darkening point it is not a reliable way of differentiating between the two homologs. Probably both darken between  $210^{\circ}$  and  $220^{\circ}$  when the temperature is rapidly raised to that point.

<sup>1</sup> Thudicum, "Die chemische Constitution des Gehirns," p. 149 (1901).

**General Statements.**—From the data presented it is reasonably certain that the two fatty acids in largest amounts in cephalin are stearic and oleic.

The evidence for clupanodonic acid is rather conclusive though not entirely so. Other methods besides the bromination one are being tried to clear up this point.

The greatest uncertainty centers around cephalinic acid. The solubilities and appearance of the bromo derivative strongly suggest linolic acid, but the bromine value is too high. The melting point and percentage of bromine indicate an impure linolenic acid or a higher homolog. Several lines of attack are being carried on the more clearly to understand this acid.

### Summary.

1. Somewhat more than one-fourth of the acids of cephalin is in the form of stearic, more than one-half oleic, one-tenth cephalinic, and one-twentieth clupanodonic.

2. From the varying amount of these acids present it is concluded that they are present in mixed cephalins, these various cephalins being closely associated.

3. There is no marked difference, either, in the kind or amount of acids in sheep and beef brain cephalins.

4. The evidence presented strongly indicates ordinary stearic and oleic acids as the principal fatty acids of cephalin.

5. The evidence for the identity of clupanodonic and cephalinic acids is not conclusive.

## THE ACTION OF ANHYDROUS ALUMINIUM CHLORIDE UPON UNSATURATED COMPOUNDS.

BY W. E. HENDERSON AND WILMER C. GANGLOFF.

Received May 10, 1916.

It is known that the product obtained by cracking petroleums with aluminium chloride under certain conditions consists very largely of saturated hydrocarbons; whereas distillation under pressure results in a large percentage of unsaturated compounds. One possible explanation of this peculiarity is that the aluminium chloride combines with any unsaturated hydrocarbons formed in the reaction and holds them back from the distillate. The simple experiment of shaking ordinary gasoline with the anhydrous chloride showed that by this treatment all of the unsaturated hydrocarbons are converted into a dark-colored sludge, and that the gasoline resulting gives no color with concentrated sulfuric acid. Petroleum ether acts in a similar way.

A careful review of the literature discloses the fact that very little work

is recorded upon the action of anhydrous aluminium chloride with unsaturated hydrocarbons. This is somewhat surprising in view of the large number of researches upon the addition products that the reagent forms with so many diverse types of organic compounds, and the rôle it plays in the Friedel-Crafts reaction. The chief researches bearing directly upon the subject are cited in the foot-note.<sup>1</sup> From this work it appears that various complex and ill-defined products have been described as resulting from passing vapors of unsaturated hydrocarbons over aluminium chloride heated to various temperatures; that solutions of aluminium chloride in organic solvents absorb such vapors; and that no well-defined products suitable for analysis have been obtained from these solutions.

We have undertaken a study of this field, and have secured a number of positive results. Inasmuch as it will be some time before the experiments now planned can be completed, it is thought best to publish a brief report upon the results already obtained.

**The Action of Acetylene upon Anhydrous Aluminium Chloride.**—Baud states that pure dry acetylene is completely absorbed by anhydrous aluminium chloride in a closed vessel, even in the cold. If heated to 70° the absorption is complete in a few minutes. A different reaction takes place when a current of acetylene is passed over the hot chloride, a reddish black sublimate forming which finally becomes black. The gas is almost all absorbed, and there is a considerable evolution of heat. At 120–130°, with a continuation of the gaseous current there is no further increase in the weight of the sublimate. To the products formed Baud assigns the formulas  $(C_{20}H_{16})_{7.}Al_2Cl_6$  and  $(C_{10}H_{16})_{7.}Al_2Cl_6$ .

We repeated this work, generating the acetylene from calcium carbide and passing the dried gas into a closed vessel containing finely powdered, freshly prepared, anhydrous aluminium chloride. No noticeable absorption occurred within several hours. Upon heating the aluminium chloride at 60–62° a reddish brown sublimate appeared, dense vapors were produced, and the sublimate soon turned black and remained unchanged after heating to 140°. Heating to 240° yielded nothing but tar. The black substance resembled pitch, and under the microscope showed no crystalline form. It was evidently a complex mixture.

**The Action of Acetylene upon Alcoholic Solutions of Aluminium Chloride.**—Dry acetylene prepared from calcium carbide was passed into a solution of aluminium chloride in absolute alcohol, and after thorough

<sup>1</sup> Friedel and Crafts, *Compt. rend.*, 84, 1392 (1877); *Ann. chim. phys.*, [6] 1, 440, 446, 449, 461, 510, 518 (1884); Adrianowsky, *Ber.*, 12, 853 (1879); Gustavson, *J. prakt. Chem.*, [2] 42, 501 (1890); Winogradoff, *Ibid.*, 37, 110 (1888); Baud, *Chem. News*, 81, 286 (1900); Perrier, *Compt. rend.*, 122, 196 (1896); *Ber.*, 33, 815 (1900); Menschutkin, *J. Russ. Phys. Chem. Soc.*, 42, 1310 (1910); Steele, *J. Chem. Soc.*, 83, 1470 (1903).

saturation for several hours the solution was set aside in a desiccator charged with acetylene. After five days small, colorless, glistening, well-formed crystals appeared. These were very soluble, hygroscopic, difficult to dry, soluble in most solvents, and they decomposed with great ease. Experiments showed that this product was not merely aluminium chloride with alcohol of crystallization. When treated with acids the crystals evolved acetylene, as was shown by the precipitation of copper acetylide from ammoniacal cuprous chloride. Many difficulties were encountered in the analysis of this and similar products. The compound loses acetylene and hydrogen chloride on standing, and in the process of drying. It is exceedingly difficult to burn the carbon by ordinary combustion methods and wet methods were resorted to. Possibly aluminium carbide is formed when the compound is heated, rendering combustion difficult. The analysis, while leaving much to be desired, rather clearly indicates the composition of the product.

Calc. for  $\text{AlCl}_3 \cdot 2\text{C}_2\text{H}_2 \cdot 2\text{H}_2\text{O}$ : Al, 12.23; Cl, 48.03; C, 21.67; H, 3.61. Found: Al, 12.47; Cl, 45.59; C, 25.70; H, 3.97.

The presence of water in the alcohol prevents the formation of any crystalline product.

**The Action of Ethylene upon Aluminium Chloride.**—The action of ethylene upon aluminium chloride has been found to be closely parallel to that of acetylene. Ethylene was prepared from ethyl alcohol and sulfuric acid at  $170^\circ$ , dried in a train of sulfuric acid and potassium hydroxide, and passed into a closed vessel containing anhydrous aluminium chloride. No noticeable absorption occurred during several hours. Upon heating, a black tarry mass was formed containing much free carbon, and no crystalline product was obtained. A solution of aluminium chloride in absolute alcohol was then saturated with ethylene, and was allowed to stand for a week in a desiccator. A well-crystallized product was obtained closely resembling the product formed with acetylene. It was very hygroscopic, lost ethylene and hydrogen chloride in drying, and decomposed with great ease. The analysis for carbon presented the same difficulties as in the case described.

Calc. for  $\text{AlCl}_3 \cdot 3\text{C}_2\text{H}_4 \cdot \text{H}_2\text{O}$ : Al, 11.58; Cl, 45.15; C, 30.56; H, 5.99. Found: Al, 12.61; Cl, 44.76; C, 30.49; H, 6.45.

In addition to those described, crystalline products have been obtained with propylene, butylene, styrolene, oleic acid, and amylene. While well-crystallized, these bodies are very soluble, are difficult to crystallize, have a considerable dissociation pressure, and are, in general, very difficult to prepare for analysis. We are not at present prepared to suggest formulas for them, but shall hope to make a more complete report at some future time.

[CONTRIBUTIONS FROM THE SHEFFIELD CHEMICAL LABORATORY OF YALE UNIVERSITY.]

**RESEARCHES ON PYRIMIDINES. LXXVIII. THE REDUCTION OF 2-MERCAPTO-6-CHLOROPYRIMIDINES.**

BY TREAT B. JOHNSON AND A. WILLARD JOYCE.

Received May 20, 1916.

In a previous paper from this laboratory Johnson and Joyce<sup>1</sup> have shown that 2-mercapto-6-chloropyrimidines (IV) can be reduced easily by the action of zinc dust with formation of the corresponding 2-mercaptopyrimidines. They prepared in this manner 2-ethylmercaptopyrimidine (I), 2-ethylmercapto-4-methylpyrimidine (II) and 2-ethylmercapto-5-ethoxypyrimidine (III). These are the only representatives known of this new class of mercaptopyrimidines. Such combinations can now be prepared easily in quantity by application of our method. In no case have we failed, thus far, to bring about a smooth reduction when we employed pyrimidine combinations containing methyl- and ethylmercapto groups in the 2-position of the pyrimidine ring. 2-Methylmercapto-6-chloropyrimidine (V) has been prepared<sup>2</sup> and we find that this undergoes reduction as smoothly as its corresponding 2-ethylmercapto compound. The yield of the reduced pyrimidine (VI), in this case, was 70% of the theoretical. A chlorine atom in position 2 also does not hinder the reduction of a halogen in the 6-position as 2,6-dichloro-5-ethoxypyrimidine is readily reduced by zinc dust to the corresponding 2-chloro-5-ethoxypyrimidine.<sup>3</sup> We have now introduced a benzylmercapto grouping into position 2, and have prepared the hitherto unknown 2-benzylmercapto-6-chloropyrimidine (VIII). The latter was easily obtained by the action of phosphorus oxychloride on 2-benzylmercapto-6-oxypyrimidine<sup>4</sup> (VII). All attempts to reduce this pyrimidine to the corresponding 2-benzylmercaptopyrimidine (IX) have so far been unsuccessful. Not only was it found to be extremely stable in the presence of zinc dust, but it was also not reduced by sodium-amalgam and zinc-amalgam. We also investigated its behavior towards hydriodic acid and found that here also the pyrimidine exhibited great stability. Owing to its weak basic properties it simply combined with hydriodic acid forming a characteristic, crystalline salt (X). This ability to form salts is a property of these mercaptochloropyrimidines which hitherto has not been emphasized by us. On warming with hydriodic acid such combinations are decomposed with evolution of mercaptans. The hydriodide of this base (X) is easily decomposed by water with dissociation into the free pyrimidine and hydriodic acid. There was no evidence of an exchange of halogens

<sup>1</sup> THIS JOURNAL, 37, 2151 (1915).<sup>2</sup> Wheeler and Bristol, *Am. Chem. J.*, 33, 437 (1905).<sup>3</sup> Johnson and Joyce, *Loc. cit.*<sup>4</sup> Wheeler and Liddle, *Am. Chem. J.*, 40, 554 (1908).

with production of 2-benzylmercapto-6-iodopyrimidine (XI) and hydrochloric acid.

While bases of the type of 2-methylmercaptopyrimidine (VI) resist further reduction by the action of zinc dust, on the other hand, when subjected to the action of metallic sodium in alcoholic solution they undergo characteristic changes. Not only is the ring completely saturated with hydrogen, but the pyrimidine cycle is finally ruptured and an aliphatic diamine is formed. 2-Methylmercaptopyrimidine; for example, is reduced under such conditions with production of trimethylenediamine (XII) and methylmercaptan. The yield of the diamine was equivalent to 60 per cent. of a theoretical yield showing that we have here a prac-

tical method of synthesizing aliphatic combinations of this type. Regarding the mechanism of this reaction it seems probable that the first phase of the transformation involves a complete reduction of the pyrimidine (VI), with formation of its hexahydro derivative represented by Formula XIII. This then might break down theoretically in two ways, namely, either undergo further reduction in the alkaline solution to mercaptan and the sulfur-free pyrimidine (XIV), which on hydrolysis would give formaldehyde and the diamine (XII), or the pyrimidine (XIII) undergo hydrolysis directly with production of the diamine (XII) and methylthiolformate (XV). The latter would then be saponified by the alkali present giving formic acid and methylmercaptan. Mercaptan was always recognized by its odor, but the formation of formaldehyde of formic acid was not established. The reaction may be expressed as follows:

An increase in the basicity of the pyrimidine molecule is brought about by the transformation of a 2-mercapto-6-oxypyrimidine into a 2-mercapto-6-chloropyrimidine and a 2-mercaptopyrimidine. The oxygen pyrimidines are extremely weak bases<sup>1</sup> and possess acid properties on account of the presence of a CO-NH grouping in their molecules. The mercaptochloropyrimidines and corresponding 2-mercaptopyrimidines, on the other hand, are insoluble in alkaline solutions. They do not contain any ionizable hydrogen and interact with acids with formation of salts. The latter are, however, unstable and easily undergo dissociation in aqueous solution. The 2-mercaptopyrimidines are also characterized by their property of forming addition products with alkyl halides. Two combinations of this type have been prepared and are represented by Formulas XVI and XVII. Both were obtained in a crystalline condition and could be crystallized from alcohol without decomposition. So far as we are aware, the corresponding 2-mercapto-6-oxypyrimidines have not been shown to form analogous

<sup>1</sup> Wheeler and Bristol, *Loc. cit.*

addition combinations with alkyl halides. The investigation of the behavior of pyrimidine compounds towards reducing agents will be continued.

### Experimental Part.

**Reduction of 2-Methylmercapto-6-chloropyrimidine with Zinc Dust. The Formation of 2-Methylmercaptopyrimidine (VI).**—The 2-methylmercapto-6-chloropyrimidine, which was used in this work, was prepared according to the method of Wheeler and Bristol<sup>1</sup> by the action of phosphorus oxychloride on 2-methylmercapto-6-oxypyrimidine. In order to obtain the best yields of the reduced pyrimidine, it was found advisable, by experience, to work with small quantities of the chloropyrimidine at a time. Our procedure was as follows: Eighty grams of the chloropyrimidine were divided into four portions and 20 grams placed in separate flasks with 40 grams of zinc dust, 100 cc. of water and 100 cc. of alcohol. These mixtures were then boiled for one-half an hour, when the excess of zinc dust was filtered off and the alcoholic filtrates combined, and then concentrated under diminished pressure. A dark-colored oil was obtained, which was extracted with ether and dried over calcium chloride. A small amount of 2-methylmercapto-6-oxypyrimidine was identified here and was formed by partial hydrolysis of the 2-methylmercapto-6-chloropyrimidine during the reduction. After removing the ether, the oil was purified by distillation under diminished pressure and boiled at 99–100° at 14 mm. pressure. This was a colorless liquid having an odor similar to that of pyridine and quinoline. On exposure to the air the pyrimidine gradually turns light brown, but this change does not take place as readily as in the case of the corresponding 2-ethylmercaptopyrimidine previously described by Johnson and Joyce.<sup>1</sup> The yield is about 70% of the theoretical. This pyrimidine, as well as the 2-ethylmercaptopyrimidine, forms salts with strong acids, the hydrochloride dissolving in water without dissociation. One part of the base dissolves in about 20 parts of cold water. This aqueous solution does not give an alkaline reaction with litmus or turmeric paper. The pyrimidine is volatile with steam. Analysis:

Calc. for  $\text{C}_5\text{H}_6\text{N}_2\text{S}$ : N, 22.22. Found: N, 22.19, 22.02.

Index of refraction:  $n_D$  at 20° = 1.5856 (Abbe). Index of refraction of 2-ethylmercaptopyrimidine:  $n_D$  at 20° = 1.5673 (Abbe).

<sup>1</sup> *Loc. cit.*

**Hydrochloride.**—This salt was prepared by passing dry hydrochloric acid gas into an ethereal solution of the pyrimidine. It crystallized in needles which melted at  $147^{\circ}$ . Analysis:

Calc. for  $C_5H_6N_2S.HCl$ : N, 17.23. Found: N, 17.1, 17.00.

**Hydrobromide.**—This was prepared by mixing strong hydrobromic acid solution with the mercaptopyrimidine. They interacted immediately with formation of a crystalline salt. This was purified by crystallization from absolute alcohol and separated in the form of rectangular prisms melting at  $187^{\circ}$ . Analysis:

Calc. for  $C_5H_6N_2S.HBr$ : N, 13.52. Found: N, 13.2, 13.31.

**The Addition of Methyl iodide to 2-Methylmercaptopyrimidine. 1,1-**

of the pyrimidine were added 2 grams of methyl iodide and the mixture allowed to stand at room temperature overnight. When examined the next morning the mixture had solidified to a crystalline mass of needles. These were triturated with cold ether and crystallized from boiling absolute alcohol. The pyrimidine separated, on cooling, in the form of irregular, prismatic rods or needles. They melted at  $146\text{--}147^{\circ}$  to a red oil. This addition product is very soluble in water. Concentrated sulfuric acid interacted with it with liberation of iodine and when the compound was treated with dilute alkali methylmercaptan was slowly evolved.

Calc. for  $C_6H_8N_2SI$ : N, 10.44. Found: N, 10.11, 10.36.

**1,1-Methylido-2-ethylmercaptopyrimidine.**—This pyrimidine was prepared in a manner similar to that employed for the preparation of the preceding addition product. It crystallized from absolute alcohol in needles which melted at  $135^{\circ}$  to a red oil. Analysis:

Calc. for  $C_8H_{11}N_2SI$ : N, 9.52. Found: N, 9.36.

**The Formation of Trimethylenediamine by Reduction of 2-Ethylmercaptopyrimidine.**—This mercaptopyrimidine is easily converted into trimethylenediamine by reduction with sodium and alcohol. The procedure was as follows: Ten grams of the 2-ethylmercaptopyrimidine were dissolved in 150 cc. of absolute alcohol and this solution then added slowly upon 20 grams of metallic sodium (2 molecular proportions). As the reduction proceeded the alcoholic solution assumed a dark red color and ethylmercaptan and ammonia were evolved. For complete solution of the sodium 100 cc. more of alcohol were finally added and the solution finally heated on the steam bath. After complete solution of the sodium,

air was blown through the mixture to expel as much ammonia as possible and the solution then subjected to steam distillation. The distillate containing alcohol and base were conducted into hydrochloric acid. After complete distillation the hydrochloric acid solution was evaporated to dryness, *in vacuo*, and the hydrochloride of trimethylenediamine purified by crystallization from 25% alcohol. In this manner it was easily separated from ammonium chloride. The salt crystallized in beautiful transparent prisms which melted at 242–243°. This same melting point is also to be assigned to the compound prepared by Fischer's<sup>1</sup> method. A mixture of the salt prepared by both methods melted at 242–243°. The yield of hydrochloride was 6.2 grams or 60% of the theoretical. Analysis:

Calc. for  $C_6H_{10}N_2 \cdot 2HCl$ : N, 19.04. Found: N, 19.00, 19.02.

**Alkylation of 2-Thiouracil with Benzylchloride. The Formation of 2-Benzylmercapto-6-oxypyrimidine (IX) and 2-Benzylmercapto-3-benzyl-6-oxypyrimidine.**—2-Benzylmercapto-6-oxypyrimidine has been described by Wheeler and Liddle,<sup>2</sup> and was prepared for our work according to their directions. We made the observation, however, that this is not the only product formed by allylation with benzyl chloride. We succeeded in isolating another derivative in small quantity, which crystallized from alcohol in colorless, flat prisms melting at 144–145° to a clear oil. The yield of this pyrimidine was about 5–10% of the theoretical and it was identified as 2-benzylmercapto-3-benzyl-6-oxypyrimidine. It was very soluble in alcohol and ether, and insoluble in water, aqueous alkali and acid solutions. Analysis:

Calc. for  $C_{18}H_{18}ON_2S$ : N, 9.09. Found: N, 8.8.

half grams of the above 2-benzylmercaptopyrimidine were dissolved in 100 cc. of concentrated hydrochloric acid, by warming on the steam bath, and the solution then evaporated to dryness. The residue was crystallized from boiling alcohol. On cooling, this thiopyrimidine separated in the form of plates, which melted at 231°. These gave a strong test for sulfur. Analysis:

Calc. for  $C_{11}H_{10}ON_2S$ : N, 12.84. Found: N, 13.00.

**Desulfurization of 2-Thio-3-benzyl-6-oxypyrimidine with Formation of 2,6-Dioxy-3-benzylpyrimidine.**<sup>3</sup>—One and two-tenths grams of the thiopyrimidine were digested for seven hours with 4 grams of chloro-

<sup>1</sup> *Ber.*, 17, 1799 (1884).

<sup>2</sup> *Am. Chem. J.*, 40, 554 (1908).

<sup>3</sup> Johnson and Derby, *Am. Chem. J.*, 40, 444 (1908).

acetic acid. The pyrimidine dissolved completely and, on cooling, the desulfurized pyrimidine separated in a crystalline condition. It crystallized from alcohol in prisms melting at  $173-174^{\circ}$  as originally observed by Johnson and Derby. A mixture of our pyrimidine and the isomeric 1-benzyl-2,6-dioxypyrimidine melted at  $140-155^{\circ}$ .

**2-Benzylmercapto-6-chloropyrimidine.**—Forty-four grams of the 2-benzylmercapto-6-oxypyrimidine were mixed with 25 cc. of phosphorus oxychloride in a distilling flask and the mixture then heated in an oil bath for about 5.5 hours. The pyrimidine dissolved completely and hydrogen chloride was evolved. The excess of phosphorus oxychloride was then removed by distillation, under diminished pressure at  $100^{\circ}$ , and the thick, viscous oil remaining behind poured upon crushed ice to destroy the last traces of phosphorus halide. After extraction with ether and drying over calcium chloride the oil was then distilled under diminished pressure. It boiled at  $210^{\circ}$  at 18 mm. On cooling, this oil solidified in the form of long prisms which melted at  $48-49^{\circ}$ . The yield was 33 grams or 70% of the theoretical. Analysis:

Calc. for  $C_{11}H_9N_2SCl$ : N, 11.84. Found: N, 11.71, 11.86.

This pyrimidine is soluble in ether, alcohol and benzene. It is insoluble in water, dilute acid and alkaline solutions and is hydrolyzed by digestion with strong hydrochloric acid with formation of uracil.

**Attempts to Reduce 2-Benzylmercapto-6-chloropyrimidine: Action of Zinc Dust.**—Five grams of the chloropyrimidine were dissolved in a mixture of 100 cc. of alcohol and 50 cc. of water, and 15 grams of zinc dust added. After boiling for 5 hours the excess of zinc was separated by filtration and the alcohol removed by evaporation under diminished pressure. The oil remaining behind was then extracted with ether and dried over calcium chloride. On evaporating the ether, unaltered 2-benzylmercapto-6-chloropyrimidine separated in the form of needles and melted at  $45-47^{\circ}$ .

**Action of Zinc Amalgam.**—Five grams of the chloropyrimidine were dissolved in a mixture of equal volumes of water and alcohol (150 cc.) and 20 grams of amalgamated zinc suspended in the solution. This was then boiled for 4 hours and the zinc separated by filtration. On evaporating the alcohol and water under diminished pressure, we obtained an oil which finally solidified and was identified as the unaltered chloride. The same result was obtained when an attempt was made to reduce the chloropyrimidine with sodium amalgam.

**The Action of Hydriodic Acid.**—Nine grams of 2-benzylmercapto-6-chloropyrimidine were melted in a flask and 15 cc. of colorless hydriodic acid (b. p.  $127^{\circ}$ ) added. There was an immediate reaction with evolution of heat and formation of a crystalline product. The entire mixture became solid. The odor of benzyliodide was also noticeable, indicating

a partial hydrolysis of the pyrimidine. The crystals, which were yellow, were filtered off, washed with ether and dried in a vacuum over sulfuric acid. They melted at  $136^{\circ}$ . A nitrogen determination showed that we were dealing with a hydriodic acid salt of the chloropyrimidine. The compound also gave tests for chlorine and iodine.

Calc. for  $C_{11}H_8N_2SCl.HI$ : N, 7.68. Found: N, 7.3, 7.26.

This salt could not be crystallized from the common solvents without dissociation. It is insoluble in ether, carbon tetrachloride and benzene, slightly soluble in acetone and very soluble in absolute alcohol. It was easily hydrolyzed by water, giving an oil which finally solidified and melted without further purification at  $45^{\circ}$ . This was identified as the original chloropyrimidine. When this was mixed with some of the chloro compound there was no lowering of the melting point. The yield of the salt was 12 grams of 84% of the theoretical.

NEW HAVEN, CONN.

[CONTRIBUTIONS FROM THE SHEFFIELD CHEMICAL LABORATORY OF YALE UNIVERSITY.]  
**STUDIES ON NITRATED PROTEINS. V. THE HYDROLYSIS OF  
NITRO-FIBROIN WITH HYDROCHLORIC ACID.**

By TREAT B. JOHNSON AND ARTHUR J. HILL.

Received May 20, 1916.

The term "Nitro-Fibroin," as we shall apply it in this paper, is the name of a modified protein which is obtained by treatment of pure fibroin, under definite conditions, with nitric acid of specific gravity 1.12. This sulfur-free protein is very easily attacked by strong nitric acid, but the reaction is not productive of consistent results unless applied under carefully regulated conditions. We have found that, if the protein be exposed to the action of acid of the above strength for a long time and at ordinary temperature ( $18-25^{\circ}$ ), a stage in the transformation is finally reached where practically no further action on the protein takes place. In other words, it has been our experience that a nitrated protein of quite definite constitution is formed, which is optically active and does not respond to Millon's test for tyrosine. This substance is obtained in the form of an orange-colored powder and the yield corresponds to about 70% of the weight of the original protein. The method of preparing this interesting product (nitro-fibroin) has already been described in a previous paper from this laboratory.<sup>1</sup>

Inouye<sup>2</sup> prepared a nitrated fibroin by the action of cold nitric acid (sp. gr. 1.12) on silk fibroin and obtained after 48 hours' treatment a yield of nitroprotein corresponding to 85-90% of the weight of fibroin taken. This product was subjected to hydrolysis with dilute sulfuric

<sup>1</sup> Johnson, Hill and O'Hara, *THIS JOURNAL*, 37, 2170 (1915).

<sup>2</sup> *Z. physiol. Chem.*, 81, 80 (1912).

acid, when he made the interesting observation that a nitrotyrosine of unknown constitution was one of the products of decomposition. Johnson<sup>1</sup> repeated this work of Inouye's and isolated, after hydrolysis, the same nitroamino acid. He showed that it is a definite combination formed by the action of nitric acid on the tyrosine in the protein and is to be represented structurally as an *o*-nitro derivative of this  $\alpha$ -amino acid as represented by Formula II.<sup>2</sup>

In our third paper on nitrated proteins<sup>3</sup> we called attention to the interesting observation that the nitration reaction—fibroin + nitric acid—can be followed qualitatively by Millon's test for only a few hours. Generally, after about 24 hours' treatment at ordinary temperature, the protein fails to respond to this characteristic reaction, indicating a fundamental change in the tyrosine phenol nucleus, and possibly the end of the first phase of the reaction. The isolation of *o*-nitrotyrosine (II) from the products of hydrolysis of Inouye's nitrated fibroin was the first definite evidence produced showing the true nature of this change. Neither Inouye nor Johnson obtained any evidence of the presence of a dinitrotyrosine (III) among the hydrolytic products of this nitrated protein.

In the light of these results it was therefore of especial interest to investigate the character of the hydrolytic products formed by complete hydrolysis of "nitro-fibroin" prepared according to the method of Johnson, Hill and O'Hara.<sup>4</sup> It was important to determine whether the tyrosine in fibroin undergoes further changes by long exposure to nitric acid (sp. gr. 1.12) with formation of 3,5-dinitrotyrosine (III), which has recently been described by Johnson and Kohmann.<sup>5</sup> Furthermore, it was also important to determine the nature of the other  $\alpha$ -amino acids which are constituents of nitro-fibroin. The complete hydrolysis of this protein has now been accomplished, and in this paper we record the results of our investigation.

### Experimental.

**The Preparation of Nitro-Fibroin in Quantity.**—The nitro-fibroin was prepared according to directions already given in the literature,<sup>1</sup> but we worked with much larger quantities than were used in our original investigation. In applying the reaction on a large scale, it is interesting to note that we again confirmed our original observation, namely, that the nitration of fibroin under the conditions described was productive of a remarkably constant amount of nitro-fibroin. From 479 g. of fibroin, dried at 100°, we obtained 345 g. of the nitrated protein or about 72% of the weight of the original silk fibroin. This result is in close agreement with those recorded in our previous paper. In other words, this yield calculated upon the basis of 20 g. of fibroin gives the figure 14.40, while in our original work we actually obtained in two experiments 14.26 and 14.20 g. of the nitro-fibroin from 20 g. of fibroin. This experiment was repeated with the same result. The nitric acid filtrates left after filtration of nitro-fibroin were saved (see below).

**Hydrolysis with Hydrochloric Acid.**—Our method of hydrolyzing nitro-fibroin was as follows: Three hundred grams of the nitrated protein, corresponding to 416.5 g. of silk fibroin, were dissolved in 1200 cc. of hydrochloric acid (sp. gr. 1.19). Solution was brought about very quickly and was attended with some foaming, but there was no evolution of carbon dioxide. This solution was then digested in an oil bath for 15 hours at a temperature of 120–130°. It was then allowed to stand at ordinary temperature for 3 days when a dense, brownish precipitate was observed to have deposited in the acid solution. The yield of this material was increased by concentration of the acid solution and then saturating the same at 0° with hydrochloric acid gas. After repeating this operation several times the precipitates were combined and decolorized by digestion in strong hydrochloric acid with animal charcoal. The material was then purified by recrystallization from the same solvent. We obtained in this manner 20 g. of pure material. This substance crystallized from hydrochloric acid in the form of characteristic yellow needles which melted with effervescence at 237°. This compound contained chlorine and proved to be identical with the hydrochloride of 3-nitrotyrosine (II) previously synthesized by Johnson and Kohmann<sup>2</sup> and also isolated by Johnson<sup>2</sup> from the products resulting from the hydrolysis of Inouye's nitrated protein with sulfuric acid.

Calc. for  $C_9H_{11}O_4N_2Cl$ : N, 10.70; Cl, 13.51. Found: N, 10.85, 10.95; Cl, 13.61.

The identity of this salt was also established by the fact that it underwent decomposition with alkali giving 3-nitrotyrosine II melting at 237°

<sup>1</sup> Johnson, Hill and O'Hara, *Loc. cit.*

<sup>2</sup> *Loc. cit.*

with effervescence. A mixture of our hydrolytic product and the synthetic 3-nitrotyrosine melted at 237°.

Our nitrotyrosine also interacted smoothly with ammonium thiocyanate in acetic anhydride solution giving 2-thio-4(3-nitro-4-hydroxybenzyl)-hydantoin (IV)

which has already been described by Johnson and Kohmann.<sup>1</sup> It melted at 238–240° with decomposition.

Calc. for  $\text{C}_{10}\text{H}_9\text{O}_4\text{N}_3\text{S}$ : N, 15.74. Found: N, 15.65.

When this 2-thiohydantoin (IV) is desulfurized with chloroacetic acid it is transformed into 4-(3-nitro-4-hydroxybenzyl)-hydantoin (V).<sup>2</sup> We applied the same reaction with our 2-thiohydantoin and obtained the same sulfur free hydantoin. It melted at 224° to a clear oil. We also obtained the same hydantoin (V) by the action of potassium cyanate on the hydrochloride of our 3-nitrotyrosine from nitro-fibroin. Two

grams of the hydrochloride of 3-nitrotyrosine were dissolved in water with 2 g. of potassium cyanate and the solution evaporated to dryness. The residue was then triturated with 15 cc. of concentrated hydrochloric acid and again evaporated to dryness. In this manner we obtained smoothly the hydantoin (V) which crystallized from hot water or glacial acetic acid in the form of rosetts of needles. They melted at 224° to a clear oil. A mixture of this product and the synthetic hydantoin melted at exactly the same temperature.

Calc. for  $\text{C}_{10}\text{H}_9\text{O}_5\text{N}_3$ : N, 16.75. Found: N, 16.62.

It is interesting to note here that during all these operations we obtained no evidence of changes indicating the presence of any 2-nitrotyrosine or 3,5-dinitrotyrosine. The dinitrotyrosine exhibits a behavior similar to that of 3-nitrotyrosine, when dissolved in strong hydrochloric acid, giving a very insoluble, characteristic hydrochloride.

**Examination of the Hydrochloric Acid Solution.**—The mother liquor containing the other amino acids of nitro-fibroin (300 g.) was concentra-

<sup>1</sup> *Loc. cit.*

<sup>2</sup> Johnson and Kohmann, *Loc. cit.*

ted, after complete separation of 3-nitrotyrosine, to a thick syrup by heating in a vacuum at 100°. Absolute alcohol was then added in excess and the  $\alpha$ -amino acids esterified according to the directions given by Fischer.<sup>1</sup> Glycocoll was obtained in large amount in the form of its ester hydrochloride. The total yield of this salt was 141.5 g. and it melted at 144°. A mixture of this material with the pure hydrochloride of ethylaminoacetate melted at the same temperature.

Calc. for  $C_4H_{10}O_2NCl$ : N, 10.05. Found: N, 9.85, 9.97.

After complete separation of the hydrochloride of ethylaminoacetate the alcoholic filtrate was concentrated by heating under diminished pressure at 100° and the excess of alcohol removed. A black, syrupy residue was obtained which was diluted with one-half its volume of water and the hydrochloric acid neutralized at a low temperature by addition of 33% sodium hydroxide solution. The free amino acid esters were then extracted in the usual manner with ether after saturating the solution with potassium carbonate.<sup>2</sup> After drying carefully and removal of the ether, we obtained 50.7 g. of oil which was fractionally distilled under diminished pressure with the following result:

Fraction 1, 53–63° at 13 mm. = 21.50 g.

Fraction 2, 63–85° at 13 mm. = 24.00

Fraction 3, 85–95° at 15 mm. = 3.00

Total = 48.5

These fractions were saponified and examined for amino acids. Alanine was the only one identified. The usual tests for phenylalanine and leucine were applied to Fraction 3, but this gave, on saponification, nearly pure alanine. From the 3 fractions were obtained 30 grams of this  $\alpha$ -amino acid.

Calc. for  $C_3H_7O_2N$ : N, 15.75. Found: N, 15.90, 15.80.

The results obtained by hydrolysis are recorded in Table I.

TABLE I.

Percentages and Amounts of Amino Acids Produced by Hydrolysis of 300 g. of Nitro-fibroin.

Glycine ester hydrochloride.	Actual glycine.	% of glycine.	Nitrotyrosine hydrochloride. <sup>3</sup>	% of nitrotyrosine	Alanine.	% of alanine.	Oxalic acid.	Percentage of nitro-fibroin accounted for as glycine alanine and nitrotyrosine.
Grams.	Grams.	%.	Grams.	%.	Grams.	%.	Grams	%.
141.5	76.0	25.36	20.0	5.74	30.0	10.0	2.78	41.10

<sup>1</sup> *Z. physiol. Chem.*, 33, 177 (1901).

<sup>2</sup> Fischer, *L.c. cit.*

<sup>3</sup> It is important to note here that this represents pure nitrotyrosine hydrochloride. The actual quantity present was larger but it could not be completely separated on account of its solubility.

**Examination of the Nitric Acid Filtrate.**—After the separation of nitro-fibroin from the nitric acid, it was thoroughly washed with water and the washings added to the original strong nitric acid solution. This was not discarded by us, but submitted to a careful examination in order to determine its contents. It was of interest to determine whether it contained any characteristic products of oxidation, formed by the prolonged action of nitric acid, and also any nitrotyrosine and other amino acid constituents of the original fibroin. In order to avoid any further oxidation this solution was concentrated by pouring into shallow glazed pans and allowed to evaporate spontaneously at a temperature of 35°. A specially constructed oven was used for this purpose and the operation hastened by passing a swift current of air over the surface of the liquid. We obtained in this manner a yellow, viscous oil containing in suspension hard, dense crystals. In our analysis of this residue we applied the methods utilized by Mörner in his examination of the decomposition products obtained by intense treatment of protein material with strong nitric acid.<sup>1</sup> He demonstrated the formation of oxalic, picric, benzoic and *p*-nitrobenzoic acids and another acid of unknown constitution (*x*-säure) as products of the reaction. Following his directions in our work we were able to establish conclusively the presence of oxalic acid only. In fact, we found that practically the entire residue apart from the oxalic acid consisted of ammonium nitrate.

In a second experiment we modified our procedure and subjected the residue, after evaporation of nitric acid, to an esterification in order to determine whether any amino acids were dissolved in the liquor. This operation was not productive of any evidence that such combinations were present. In fact, after extraction with ether in the same manner and evaporating the solvent only a very small amount of resinous material was obtained. In other words, the nitric acid solution contained only end products of oxidation.

**Specific Rotation of Nitro-Fibroin.**—Fibroin is optically active and its rotatory power has been carefully measured by Vignon.<sup>2</sup> This investigator used hydrochloric acid as a solvent for his protein and determined the specific rotation of fibroins from nine different sources. His results were remarkably constant. This protein in every case was laevorotatory and the specific rotation ranged from  $-39.40^\circ$  to  $-48.20^\circ$ . We now find that our nitro-fibroin is likewise laevorotatory and that the specific rotation is about the same as that of pure fibroin. We obtained the values  $[\alpha]_{17}^D = -43.39^\circ$  and  $-44.10^\circ$ . Solution of the nitro-fibroin was effected by dissolving a weighed amount of the protein in 50

<sup>1</sup> *Z. physiol. Chem.*, **95**, 263 (1915).

<sup>2</sup> *Compt. rend.*, **113**, 802 (1891); **114**, 129 (1892); *Bull. soc. chim.*, [3] **7**, 139, 773, 799 (1892).

cc. of concentrated hydrochloric acid at  $0^{\circ}$  and then diluting to 100 cc. with distilled water. The solution was then filtered to clarify it. Several rotations were taken at  $17^{\circ}$  and remarkably constant results were obtained. In fact, the measurements ranged between the values recorded above.

While nitro-fibroin was found to be optically active, on the other hand, the alanine and 3-nitrotyrosine obtained by hydrolysis were both optically inactive. In this connection it is interesting to note that 3-nitrotyrosine, prepared from natural tyrosine (from silk) by action of nitric acid,<sup>1</sup> is likewise optically inactive.

### Summary.

Nitro-fibroin<sup>2</sup> has been hydrolyzed by digestion with hydrochloric acid and 41.10 per cent of its molecule accounted for in the form of glycocoll, alanine, and 3-nitrotyrosine. The protein is optically active, but on hydrolysis leads to the formation of optically inactive alanine and 3-nitrotyrosine. The relative proportion of tyrosine to alanine and glycocoll in silk fibroin is 1 : 2.1 : 3.6, while in our nitro-fibroin the ratio of nitrotyrosine to alanine and glycocoll is 1 : 1.7 : 4.4.

Tyrosine linked in fibroin is not attacked by nitric acid of specific gravity 1.12 at ordinary temperature with substitution of two nitro groups *ortho* to the phenolic hydroxyl group of this amino acid.

NEW HAVEN, CONN.

[CONTRIBUTION FROM THE BUREAU OF PLANT INDUSTRY.]

## VOLATILE OIL OF EUTHAMIA CAROLINIANA (L). GREENE.

By G. A. RUSSELL.

Received May 2, 1916.

*Euthamia Caroliniana* (L). Greene (Family Compositae), is found growing in moist, sandy old fields throughout the United States from Massachusetts to Florida and west as far as Texas. The plant is indigenous to these states and occurs in greatest abundance near the coast, especially in Florida. It is rarely ever found on new land or in woods, but is very frequently found in abundance in old, moist lake bottoms or abandoned fields. It flowers from September to November and each plant produces an abundance of small lemon-yellow blossoms.

**Distillation of the Volatile Oil.**—On September 8, 1914, Mr. S. C. Hood, scientific assistant in charge of the Florida station of the Office of Drug and Poisonous Plant Investigations of the Bureau of Plant Industry, distilled 83 kilograms of the fresh herb gathered just previous to the flowering stage. The material was gathered in old fields adjacent to the city of Orlando in Orange County, Fla. While yet in the fresh unwilted

<sup>1</sup> Johnson and Köhmann, *Loc. cit.*

<sup>2</sup> Johnson, Hill and O'Hara, *Ibid.*

state the plants were distilled and yielded 576 g. of oil. The yield calculated with reference to the fresh herb was 0.693%. The oil was pale yellow in color and possessed a pleasant aromatic odor.

On January 11, 1916, a chemical examination of the oil was undertaken. The color had not changed on storage. The odor was characteristic of the plant when crushed between the fingers, somewhat sweetly aromatic and not unpleasant. The taste was acrid, slightly bitter and left a strong terebinthinate after-taste manifested at the base of the tongue.

**Physical and Chemical Constants.**—The specific gravity of the oil at 23° was found to be 0.8587. The low figure pointed to a predominance of terpenes in the composition of the oil. The index of refraction was 1.4805 and the specific angle of rotation at 23° was  $-10^{\circ}48'$ .

No free acids were present in the sample of oil examined. The saponification value was 6.35, which is equivalent to 2.10% of esters calculated as acetate of  $C_{10}H_{18}O(CH_3COOC_{10}H_{17})$ . The acetylation value was 25.3, which on calculation reveals 7.01% of alcohols in the original oil. The ester number of 6.35 is equivalent to only 1.66% of alcohols. There are, therefore, 5.35% of free alcohols (as  $C_{10}H_{18}O$ ) in the original oil.

**Solubility of the Oil.**—The oil was readily soluble in 6 volumes of 90% alcohol and clear in excess. It was also soluble, with slight cloudiness, in 9 volumes of 70% alcohol, and did not become clear on adding an excess of 50 volumes. The solubility results all point to a considerable quantity of terpenes present in the oil.

**Tests for Phenols and Aldehydes.**—Five cubic centimeters of oil were shaken with a 5% solution of sodium hydroxide and the mixture allowed to stand for twenty-four hours. No diminution was noted in the volume of oil. The alkaline solution was then removed, acidified with sulfuric acid and distilled with steam. The distillate tested with ferric chloride gave negative results. There were no phenols present in the sample of oil examined.

A quantitative test with Schiff's reagent revealed the presence of aldehydes. The characteristic purple color was produced after the mixture of oil and reagent had stood for about thirty minutes. A small amount of aldehydes was present in the oil.

**Combined Acids in the Oil.**—A portion of the oil was saponified with alcoholic potassium hydroxide; water was added and the whole heated on a water bath until the alcohol was expelled. The oil which separated out was removed and the aqueous alkaline solution shaken out with ether to remove any adhering oil. The alkaline solution was then reduced to a small volume on a water bath, treated with an excess of sulfuric acid and distilled with steam. The distillate was found acid to litmus and possessed a sharp though not a marked disagreeable odor. The distillate

was neutralized with 0.02 *N* potassium hydroxide and precipitated with 0.1 *N* silver nitrate. Reduction of the silver salt took place almost immediately. From the odor of the distillate, the nonseparation of oily globules on the same, and the quick reduction of the silver salt, the conclusion is drawn that the combined acid or acids present are low in carbon content and consist probably of esters of acids lower in carbon content than propionic acid.

**Fractionation of the Oil.**—A portion of the oil was first saponified and then fractionated under atmospheric pressure. Fractionation was carried on in a 200 cc. round bottom flask fitted with a Hempel distilling column having a neck 10 centimeters in length from constriction to delivery tube. The neck was filled three-fourths full with glass beads. Heat was applied by means of an air bath. An Anschütz thermometer was used and no corrections of temperatures were made.

TABLE I.—FRACTIONATION OF THE SAPONIFIED OIL.

Fraction.	Temperature.	Per cent. distilled.	Color.	Odor.	Density at 23°.	$[\alpha]_D$ at 23°.	$N_D$ at 23°.
1	170°	1.52	Water white	Slight odor of pinene	0.7992	...	1.4663
2	170–175°	51.44	Water white	Sweetly aromatic	0.8414	–3° 3'	1.4756
3	175–177°	18.04	Water white	Sweetly aromatic	0.8431	–4° 6'	1.4770
4	177–179°	9.42	Water white	Sweetly aromatic	0.8461	+13° 0'	1.4770
5	179–185°	0.50	Light yellow	Somewhat decomposed	..	...	..
6	185°+	19.58	Dark brown	Decomposed	..	...	..

Since the results obtained by fractionating the saponified oil pointed to the presence of an abundance of one constituent in this oil, a small portion of the original oil was fractionated under atmospheric pressure. The same distilling apparatus and the same source of heat was employed as in the fractionation of the saponified oil.

TABLE II.—FRACTIONATION OF THE ORIGINAL OIL.

Fraction.	Temperature.	Per cent. distilled.	Color.	Odor.	Density at 23° C.	$[\alpha]_D$ at 23°.	$N_D$ at 23°.
1	176°	50	Water white	Sweetly aromatic	0.8435	–2° 6'	1.4742
2	176–180°	25	Water white	Sweetly aromatic	0.8660	+9° 36'	1.4814
3	180°+	25	Yellowish brown	Slightly decomposed	..	...	..

A third portion of the original oil was then fractionated under 45 mm. of pressure and eight fractions secured. Heat was applied by means of an air bath and the same distilling apparatus used as in the previous fractionations.

**Examination of the Fractions.**—Fraction 1, which possessed a slight odor of pinene was tested by means of the nitrosochloride reaction.<sup>1</sup> A deep blue coloration was obtained on adding 22% of the prescribed amount of hydrochloric acid. On further addition of this reagent the color disappeared. The pinene in the oil is present only in a minute amount.

<sup>1</sup> O. Wallach, *Annalen der Chemie*, Vol. 245, p. 251.

TABLE III.—FRACTIONATION AT THE ORIGINAL OIL UNDER 45 Mm. PRESSURE.

Fraction.	Tem- perature.	Per cent. distilled.	Color.	Odor.	Density at 23°.	$[\alpha]_D$ at 23°.	$N_D$ at 23°.
				Slight odor of			
1	79-91°	5	Water white	pinene	0.8438	.....	..
	91-92°	12					
	92-93°	13					
	93-94°	17.1					
	94-95°	5					
2	91-95°	47.1	Water white	Aromatic	0.8439	— 3° 36'	1.4765
	95-96°	8					
	96-97°	6					
	97-98°	2.9					
	98-100°	1.0					
3	95-100°	17.9	Water white	Aromatic	0.8444	— 3° 36'	1.4795
4	100-105°	5	Water white	Aromatic	0.8470	+ 5° 18'	1.4844
5	105-115°	5.4	Light yellow	Aromatic	0.8669	+19° 48'	1.4878
6	115-150°	4.6	Light yellow	Sweet aromatic	0.9056	—34° 18'	1.4937
7	150-180° <sup>1</sup>	5	Yellow	Slightly decom- posed	0.9286	—63° 18'	1.5042
8	Residue	10	Dark reddish brown	Slightly decom- posed	..	.....	..

A purple color developed on allowing a portion of the fraction to stand in contact with Schiff's reagent for thirty minutes, indicating a trace of aldehydes.

Fractions 2, 3 and 4, which contain the major portion of the fractional oil, were examined for dipentene. Wallach<sup>2</sup> gives the following constants for dipentene: B. p., 177-178°; Sp. gr., 0.845 at 20°.

The boiling point of the major portion of the oil was found to be 170° to 179°, 80.42% passing over at these temperatures. The specific gravity of the fractions obtained at atmospheric pressure was from 0.8414 to 0.8461 at 23°. A more careful fractionation at 45 mm. pressure gave fractions whose specific gravity at 23° was 0.8439 to 0.8444, which corresponds very closely with those stated in the literature.

On shaking a portion of the fractions with an equal volume of concentrated sulfuric acid, a strong odor of hydrogen sulfide was developed, indicating the presence of dipentene.<sup>3</sup>

On treating these fractions with alcoholic sulfuric acid at a temperature of 50° a compound was obtained that had no optical activity.

A weighed amount of each of the fractions was treated with bromine. After standing for several days crystals separated out. These crystals of dipentene tetrabromide recrystallized from acetic ether melted at 123-124°. The fraction consist mainly of dipentene.

<sup>1</sup> At 180° decomposition becomes marked as indicated by a sudden fall in the temperature.

<sup>2</sup> *Ann.*, 245, 197.

<sup>3</sup> Heusler and Pond, "Chemistry of the Terpenes," 89 (edition).

On shaking Fraction 5 with an equal volume of concentrated sulfuric acid a slight odor of hydrogen sulfide was noted. On treating with bromine a slight amount was absorbed, but no crystals separated on standing. Testing for limonene by means of the nitrosochloride gave a blue coloration at first, but this color rapidly disappeared. Evidently there is little, if any, limonene in the oil.

Fractions 6 and 7, which consist of 9.6% of the original oil, are levorotatory and of relatively high specific gravity. Their composition was not established.

### Summary.

The sample of volatile oil of *Euthamia caroliniana* (L). Greene examined, consists mainly of dipentene with a trace of pinene and possibly a small amount of limonene. No free acids were present, although the oil had been distilled and stored for about 15 months. A small percentage of combined acids, probably formic and acetic were present. Esters were present to the extent of 2.10% calculated as  $\text{CH}_3\text{COOC}_{10}\text{H}_{17}$ . The presence of aldehydes was established by means of Schiff's reagent. The total amount of alcohols present was 7.01%, of which 5.35% are free, and 1.66% combined. In addition to the compounds identified, a compound or compounds having levorotatory properties and a comparatively high density, are present to the extent of approximately 10%. That portion of the sample of oil that boiled above  $180^\circ$  at 45 mm. pressure with decomposition constitutes approximately 10% of the volume of the original oil.

BUREAU OF PLANT INDUSTRY,  
WASHINGTON, D. C.

---

## THE CHEMICAL COMPOSITION OF OSCILLARIA PROLIFICA.

By B. B. TURNER.<sup>1</sup>

Received April 4, 1916.

This plant, one of the *Cyanophyceae*, was first brought to the attention of the previous authors in connection with the systematic examination of the public water supplies of Massachusetts under the direction of the State Board of Health. This study was undertaken and carried on for a number of years prior to Mrs. Richards' death, because the plant is a type of blue-grass alga that has caused much trouble at water works and to consumers. It was felt that by a study of the plant some plan could be devised for successfully dealing with the class.

The life history and chemical composition of the alga have already been the subject of three papers.<sup>2</sup> It is there described how the alga

<sup>1</sup> This work was made possible through a fund established as a memorial to the late Ellen H. Richards.

<sup>2</sup> Isabel F. Hyams and Ellen H. Richards, *Technology Quarterly*, 14, 302 (1901); 15, 308 (1902); 17, 270 (1904).

grew in great quantities in the water of Jamaica Pond near Boston and contaminated the water supply, till it was destroyed by treatment with copper sulfate. The present paper is a continuation of the work on the chemical constitution of the organism begun by the former authors, and many of the lines followed were suggested by them.

The material available at this time consisted of some kilograms of the dead alga, partly dried and partly preserved in various liquids, particularly in alcohol and in glycerol. Some of the samples labelled "fermented" had evidently been put up after undergoing partial decay on exposure to air. As the samples were all several years old, it was not possible to be sure than some of the smell and fermentative processes which had gone on in those samples free from preservatives, were not partly due to moulds and other organisms which had grown somewhat upon the dead material. It is not believed, however, that the changes from this source, in the tightly-closed bottles, had been great.

**Composition in General.**—Using the ordinary methods of analysis of foodstuffs, it was found that the air-dried material contained 9.7% of moisture and 6.4% of ash, in close agreement with earlier work. A small part of the latter is due to fine sand unavoidably collected with the alga.

The proportion of nitrogen was found by the Kjeldahl method to be 7.4%, equivalent to 46.25% of protein by the usual factor of 6.25. The dried alga was next extracted with ether in a Soxhlet's apparatus, whereby 2.2% was removed. The extract contained some chlorophyll and a very small amount of fat.

The remaining 35.5% consisted principally of carbohydrates, as will be shown later, along with which would be included the more or less insoluble and indigestible substances usually classed as "fiber."

**Extractions with Solvents.**—Since ether extracts comparatively little, in order to study the nature of the material extracted it was necessary to submit a large quantity of the alga to the action of the solvent.

For this purpose an apparatus was devised by which any ordinary flask could be used and an intermittent flow obtained as in the Soxhlet extractor. As it is thought that this may prove useful to other investigators who have to work with large quantities of material, it is here described in detail.

**New Form of Extraction Apparatus.**—In order to obtain the same action as in a Soxhlet's extractor without using a flask having an outlet or side tube below the level of the neck, it is only necessary to use a siphon with equal limbs and upturned ends, so as never to run dry, at the height of the upper level to which the flask is to be allowed to fill, enclosed in another siphon, the inner limb of which reaches to the bottom of the flask, the outer limb being still lower. The air in the outer siphon, above the level of the ends of the inner siphon, is always at the same pressure in

both limbs, since they communicate freely, and this pressure varies with the action of the outer siphon, becoming lower by the expansion of the enclosed air as the liquid in the flask runs down when the siphon is in action, just as the pressure of a bubble of air trapped in the bend of an ordinary

Fig. 1.

siphon would do. The principle and manner of action of the siphon is shown diagrammatically in the accompanying sketch. The inner siphon, once filled, will remain full of liquid since the open ends A and A' are on the same level 1 and higher than the bends down which the liquid would have to flow to empty the siphon. As the liquid accumulates in the flask, the outer siphon being empty and the outer limb open to the air at C, it will rise in the limb AB level with the surface of the liquid in the flask, till it reaches level 2, a little above that of the end A when the inner siphon will come into action and carry the liquid over to A', and so fill the outer limb A'C. This will reduce the pressure of air in the upper part of the outer siphon, carrying over the extra volume due to expansion and the liquid will now be drawn out of the flask as by an ordinary siphon, flowing up to A even when the level in the flask has sunk below level 1, by atmospheric pressure, passing over to A' by the inner siphon and then descending to C. This will, obviously, continue till the flask is emptied down to level 3 when air will enter at B, and passing by the upturned end of the inner siphon A, restore the atmospheric pressure in the outer siphon causing the outer limb A'C to empty itself, when the action of the siphon will be broken, allowing the liquid again to accumulate gradually in the flask till it once more reaches level 1. This double siphon will therefore act just like the intermittent siphon in a Soxhlet apparatus, though there is no communication through the walls of the flask below the level of the neck.

In practice, the siphon is made as in the accompanying sketch, the upturned ends of the inner siphon being replaced by cups at A and A', which rest by means of small knobs of glass fused to them, on the constricted part of the outer tubes without closing the same. At D and D', the inner tubes are fused into the wider tubes, which are connected at E and F by a cross tube sealed into both. It was also found advan-

tageous to have at G, where the narrower is joined to the wider part of the inner limb, a small jet, projecting inwards, and turned a little to one side so that when the siphon empties, the inrush of air from B may be divided into small bubbles and directed past the cup at A without risk of forcing its way into the inner siphon, as may happen if the free passage of the bubbles is obstructed. The outer tubes must not be too wide, nor the inner ones too narrow, as a large volume of air in the outer siphon delays, by its expansion, the filling of the outer limb A'C, while, if the inner tubes are not wide enough to allow a fairly rapid flow of liquid from one cup to another, the outer limb may not fill at all, but the liquid may continue gradually trickling over, in which case the level of liquid in the flask cannot be drawn down below that of the cups. When properly proportioned the apparatus works well for long periods. The stopcock K is introduced for convenience in filling. If the siphon is fitted up so that V is beneath the level of liquid in the outer flask or reservoir, then as soon as the inner flask fills up to the level of B, a slight suction through K will fill the inner siphon, when K is closed and the subsequent action is automatic.

Fig. 2.

A form of the same apparatus which is easier to construct, may be made by using corks at D and D' in place of the sealed joints, and making the outer siphon in two parts connected by a rubber joint on the tube EF.

**Extraction with Alcohol.**—Extraction of the air-dried material with petroleum spirit (boiling at 40–60°) gave only about 0.1% of extracted matter, and ethyl ether extracted, as stated above, only about 2.2%.

Extraction with alcohol yields larger quantities of material.

The samples of *oscillaria* which had been standing several years in "strong" alcohol still contained a large amount of substance which could be extracted by that solvent. A portion of this partially extracted alga, after draining off the liquid, which weighed 25 g. when air-dry, was triturated in a mortar with successive quantities of about 30 cc. of absolute alcohol as long as the green color remained. After about twenty such operations, the combined extracts were mixed and an aliquot part evaporated to dryness. In this manner 1.66 g. was found to have been ex-

tracted. Allowing for moisture in the air-dried sample, and loss in the process of decanting and filtering, about 7 to 8% of the substance is seen to be soluble in cold absolute alcohol.

If the alga is treated with hot alcohol containing some water, the amount extracted is not so great. In four treatments of 100 g. of dried alga with 150 to 200 cc. of 80% alcohol, the total filtrate contained only 2.9%. If this treatment is now followed by absolute alcohol, very little more is extracted, about 0.1%. The larger amount extracted in the cold appears to be due to some coagulation, or other change, caused by the heat, which renders some constituents insoluble.

Cold water in repeated treatments extracted about 12.5%. If the aqueous extraction was preceded by alcohol, the amount withdrawn by the water was a little less. In four extractions of a lot of 100 g., following on the treatment with 80% alcohol and absolute alcohol described above, a total of 12.18% was obtained.

Boiling water acting directly on the original *oscillaria* extracted very little, but a characteristic swelling of the mass occurs to a voluminous jelly, about ten times the volume originally occupied by the solid in the loose, moist state. At the same time, the filtrate which first comes through soon gelatinizes. The carbohydrate of the alga seems to consist largely of a pectin-like substance.

The cold water extract is of a pale straw color, and rotates the plane of polarization of light to the right. It gives no precipitate on boiling the slightly acidified solution, but gives a slight yellow coloration with nitric acid. Saturation with ammonium sulfate causes a precipitate to form, as does phosphotungstic acid. Proteoses appear, therefore, to be present. The chief constituent present is apparently a carbohydrate which is dextrorotary but has little action on Fehling's solution until hydrolyzed by boiling with acids, when it causes copious reduction. The same action reduces the positive rotation, in case of prolonged treatment with acid, to zero or somewhat below.

The residue from aqueous extraction was then treated with acids. Dilute hydrochloric or sulfuric acid (1 to 2%) acts on the carbohydrate present very slowly. Accordingly, recourse was had to 5% sulfuric acid and digestion on the water bath (at about 96°) for from 6 to 10 hours at a time. This process not only hydrolyzed and dissolved carbohydrates but also decomposed proteins and the resulting liquid therefore gave a copious precipitate with phosphotungstic acid.

**Carbohydrates.**—The following experiments indicate the nature of the carbohydrates present. One hundred grams of air-dried *oscillaria* were extracted with 600 cc. of distilled water, protecting the extract from bacteria by a little toluene. The filtered extract, after precipitation with basic lead acetate and removal of excess of lead by  $\text{Na}_2\text{CO}_3$  ( $\text{H}_2\text{S}$  leads to solu-

tions which are almost impossible to free from colloiddally suspended lead sulfide) and neutralizing contained by Fehling test, reducing sugar equivalent to 0.171 g. dextrose. The rotation was  $+0.40^\circ$  for 1 decimeter.

Other similar aqueous extractions showed an average rotation of about  $+0.4^\circ$  and a cupric reducing power of about 0.001–0.002 g. per cc.

The residue from the aqueous extraction was then treated with successive quantities of about 800 cc. 5%  $\text{H}_2\text{SO}_4$  on the water bath for periods of about 10 hours. The first acid extract neutralized with  $\text{CaCO}_3$  and filtered measured about 500 cc. and showed the high rotation  $+2.35^\circ$ . After removal of sulfates by  $\text{BaCl}_2$  addition of basic lead acetate gave a copious, flocculent white precipitate. After removing excess of lead with  $\text{Na}_2\text{CO}_3$  and neutralizing, the solution, made up to 500 cc. in a measuring flask, showed a rotation of only  $+0.965^\circ$ . This solution contained 0.0476 g. per 1 cc. total solids, and had a reducing power equivalent to 0.005 g. dextrose per 1 cc., or a total of 2.5 g. By further heating for 6 hours with 5%  $\text{H}_2\text{SO}_4$ , its rotation was reduced to  $+0.475^\circ$  (for the same volume) and its reducing power rose to 0.0075 g. per 1 cc. of the original volume.

By heating with phenylhydrazine hydrochloride and sodium acetate on the water bath for several hours, a small quantity of a crystalline precipitate was obtained from the above solution which showed a rotation of  $+2.35^\circ$ . This, when crystallized from 50% alcohol with a little pyridine, melted, when rapidly heated, at  $217\text{--}218^\circ$  (corr.). Recrystallized from the same solvent, it formed beautiful clusters of very minute yellow needles, and melted sharply at  $217^\circ$ . The quantity obtained was too small for complete analysis, or further investigation, but a microkjeldahl analysis with 0.0056 g. of the once crystallized substance gave 0.00062 g. nitrogen, equivalent to 11.7%. This agrees with the formula of a hydrazone of a hexose ( $\text{C}_6\text{H}_{12}\text{O}_5\cdot\text{N}_2\text{HC}_6\text{H}_5$  N = 10.37%), or the osazone of a disaccharide ( $\text{C}_{12}\text{H}_{20}\text{O}_9\cdot(\text{N}_2\text{HC}_6\text{H}_5)_2$  N = 10.77%), rather than an osazone of a hexose ( $\text{C}_6\text{H}_{10}\text{O}_4\cdot(\text{N}_2\text{HC}_6\text{H}_5)_2$  N = 15.64%), but no known compound could be found with this melting point, containing less than two phenyl hydrazine groups to one (monosaccharide) sugar radical. Inactive  $\alpha$ -acrosazone, with the last formula, melts at this temperature, while a galaheptose-bisphenylhydrazone (N = 14.43%) melts at about  $218^\circ$ . The high positive rotation of the above solution seems therefore to be due to a disaccharide of unknown composition which, on further hydrolysis, is slowly split up into monosaccharides with a much smaller rotation. The slowness of hydrolysis negatives the existence of any disaccharide such as maltose or galactose, and as solutions with a negative rotation of any considerable amount were not obtained (see below); this still further excludes the presence of saccharose.

Qualitative tests for pentoses with phloroglucin and orcin gave nega-

tive results, as also did the resorcin test for levulose (and indirectly, for saccharose).

**Volatile Matter.**—As the unpleasant odor acquired by the water in which the oscillaria was found was one of the reasons on account of which its investigation was first begun, a method was sought by which the volatile matters might be isolated. The smell of the unfermented oscillaria, in the dry state, is pungent but not unpleasant, and seems to be due to the aromatic substance soluble in petroleum spirit.

The fermented oscillaria, both that which had been put up in glycerol and that bottle without preservative, had a smell of decaying proteins and bad cheese. A quantity of the former was placed in a large flask, and the volatile substance present driven over with steam. The first portions of the distillate had the odor of feces, but later on, the smell changed to that of Limburger and Roquefort cheese, while it finally became more spicy, something like dried herring. The presence of indole and skatole were suspected in the first runnings, so these were shaken with ether. On filtering and evaporating the ether, only a small residue remained, from which the fecal odor had nearly disappeared, and no positive test for skatole could be obtained. The residue was chiefly of a fatty nature and showed microscopic needles. Indole and skatole, if present, as was strongly indicated by the smell, were plainly present in only very small quantities, and on account of their evanescent nature, the attempt to isolate them was not pursued further.

The bulk of the volatile substance present, which formed the chief cause of the offensive odor, consisted of fatty acids. By systematic extraction with ether of large quantities of steam distillate, two or three grams of these were obtained. An analysis of the barium salt showed that the acid was chiefly butyric.

**Saponin.**—The presence of a saponin-like substance in oscillaria prolifica is mentioned in an earlier paper,<sup>1</sup> "which is set free" (from the alga in its natural habitat) "to such an extent that the water froths whenever stirred by the wind, as if it contained a liberal supply of soap bark." A similar tendency to froth is easily noticed in the aqueous extract of the dried or preserved alga. But the suggestion that this tendency is due to a true saponin has not been confirmed by subsequent work. Various substances of the nature of dextrans, etc., might produce a similar result.

Since methyl alcohol constitutes the best solvent for saponin, 200 cc. were allowed to stand eleven days on 75 g. of dried, powdered oscillaria which had been previously extracted with ether. After filtering the deep green extract, ether was added to precipitate the saponin. A small quantity of a white gelatinous precipitate came down on adding about one volume of ether and this was increased a little by adding another volume

<sup>1</sup> *Tech. Quart.*, 15, 309-310 (1902).

of ether. A similar precipitate in about the same quantity was obtained by the action of methyl alcohol on the original dried oscillaria. This was tested for saponin in the following ways: (1) Basic lead acetate added to a solution of the above white substance gave no precipitate; (2) concentrated barium hydroxide solution gave a slight turbidity to a fairly strong solution; (3) ferric chloride and a ferricyanide was slowly reduced in the cold, somewhat faster on heating. This would agree with the presence of some saponin, as would the following two tests: (4) Mercuric chloride on heating and cooling gave with the substance in question a white turbidity; it was, however, *not* blackened by ammonia; (5) similarly, Nessler's solution was turned yellow, and, finally, gray, by this substance on heating; (6) tannic acid gave a considerable white precipitate; (7) no blue or green color, or fluorescence, however, was obtained on adding concentrated  $\text{H}_2\text{SO}_4$  with a little alcohol, likewise (8) no green color appeared on exposure to air of a solution of the substance in concentrated  $\text{H}_2\text{SO}_4$ ; (9) lastly, the hemolysis test proved negative in three to four hours; a slight hemolysis after sixteen hours was no more than would be observed with water alone. On the whole, the indications for the presence of an appreciable quantity of saponin in the oscillaria seem very doubtful. The substance isolated by methyl alcohol, which may also be the cause of the frothing, appears to be either a complex polysaccharide or more probably a glucoside. It does not reduce Fehling's solution directly, but does so strongly after it has been hydrolyzed by boiling for one-half to one hour with about 5%  $\text{HCl}$ .

A similar substance was found as a considerable constituent in all the alcoholic solutions in which the oscillaria had been preserved. These, though originally "strong" alcohol, had been diluted by the water in the fresh alga, so that they were not much more than 80%, in which strength saponin and similar substances are readily soluble.

**Crystals.**—A large part of the research was devoted to the search for definite substances which might be separated from the alga by crystallization. The various procedures need not be repeated in detail. With the exception of a few crystals of ammonium magnesium phosphate, only one crystalline substance was found and that in very minute proportion. This was obtained from the aqueous extract of the fermented oscillaria after it had been distilled with steam. The extract was treated with excess of basic lead acetate, a large quantity of gummy, brown precipitate was filtered off, the excess of lead removed with  $\text{H}_2\text{S}$  and the latter boiled off, and the filtrate then treated with about 2.5 volumes absolute alcohol, which brought down another amorphous precipitate. The filtrate from this was treated with ether till a slight turbidity was formed and then allowed to stand. Among the gummy drops which settled out in one or two days were found minute white spherules and star-shaped aggregates of

almost microscopic needles. By resolution of these in a very little water and reprecipitation with alcohol, and ether, they were obtained nearly free from gum, and the final separation was effected by rapid washing with water and decantation. By the microkjeldahl process described below, they were found to be free from nitrogen. When ignited in a little platinum boat, the ash was found to be 17.4%, consisting almost entirely of magnesia. The equivalent weight of the acid, assumed to be monobasic, is about 118, which agrees with that of caproic acid,  $C_6H_{14}O_2$ .

**Coloring Matter.**—Extraction with alcohol or ether of the air-dried alga, as well as that which had been preserved in alcohol, gave a brownish green solution characterized by a spectrum with five absorption bands. That this is caused by a mixture of two or more substances is shown by the separation of the bands, as indicated below. The original spectrum is as follows, the first four bands being given in the order of their intensity:

I. A very dark band with sharp edges in the red, extending in solutions of a medium depth of color, from about wave length 680 to 645  $\mu$ .

II. A broad, fairly dark band in the bluish green, shading off gradually from about 513 to 493.

III. A fainter band in the orange, shading off, 625 to 600.

IV. A faint band in the green, 540 to 530.

V. A strong end absorption beginning fairly sharply at about 440.

Of these, I, III, IV and V agree with Bands I, II, IV and VI, as given for crystallized chlorophyll by Willstätter.<sup>1</sup> Like other samples of "chlorophyll," this substance can be separated into a green coloring matter (the purified chlorophyll) and one or more yellow substances, such as have been described as xanthophylls.

Traces of yellow and red colors were observed at various times when the oscillaria was treated with solvents, but in too small amounts to allow identification.

The most interesting color obtained, however, was seen to a slight extent (perhaps as a colloidal suspension) in the aqueous extract of the air-dried material, which in bulk showed the violet color described in a former paper,<sup>2</sup> reproduced as No. 3 on Plate 1, but was present in notable quantity only in one bottle in which the oscillaria had been preserved under glycerol. Attempts to reproduce this by making glycerol extracts of the dried material all failed. Probably it is necessary to extract the fresh oscillaria with glycerol at a certain state of its growth, or exposure to air, or it may be that some ferment is concerned in the liberation of the color, which has lost its activity in the years since the alga was collected. Adding a little of the colored solution to a fresh glycerol extraction did not affect the result.

<sup>1</sup> *Handbuch d. Bioch. Arbeitsmethoden* II, p. 683.

<sup>2</sup> *Tech. Quart.*, 17, 3, 271 (1904).

The glycerol solution already mentioned was a deep bluish green by transmitted light, but was characterized by an intense red fluorescence, so that when looked at in bulk, or even in thin layers when illuminated from the side or behind the observer, it looked like blood. This fluorescence was examined with monochromatic illumination and showed a narrow band in the red at  $670\mu\mu$  which appeared unchanged in position when the wave length of the illumination varied, provided, as is required by theory, that the latter was shorter than that of the band; for longer wave lengths of illuminating light, the fluorescence disappeared.

The absorption spectrum of the blue-green solution was as follows:

I. Very dark band in red with a sharp edge on the red side at about 658 (shading at most to 660 or 662), and shading very gradually on the yellow side from about 643 almost to the D lines (*i. e.*, to about 600).

II. A very faint band in the yellowish green at about 577 to 565.

III. End absorption commencing about 450 and strong from 440 onwards.

Of these the third seems to be due to admixture with a green "chlorophyll," like that already described, as it disappears on purification, as appears in the following; the second agrees in position with Band III of Tswett's<sup>1</sup> Chlorophyllin  $\alpha$ .

Both ether and alcohol precipitate the color, but it is changed in the process. The precipitate has a purple hue but is much less intensely colored than the original solution. Acids and alkalies also destroy the color. Heating to about  $70^{\circ}$  causes a highly colored dull blue flocculent precipitate to collect, as also does the addition of lead acetate, but in neither case can the coloring matter be redissolved unchanged.

When the glycerol solution is mixed with about two-thirds of its volume of a saturated solution of ammonium sulfate, the coloring matter is precipitated, which precipitate may be readily redissolved, after filtration, on adding a little distilled water. It then shows a pure blue color and the same intense red fluorescence. Repetition of the process requires a greater concentration of ammonium sulfate, as the glycerol has been removed, but the substance comes down readily on saturating its aqueous solution with the salt. In this way, it may be obtained in solution free from glycerol.

The color may be purified by precipitation with ammonium sulfate, and the spectrum of this purified solution, which is a pure and very intense blue in color, strongly resembling in appearance the color of cuprammonium hydroxide, shows Band I as described, very strongly without the end absorption III.

This blue coloring matter with the strong red fluorescence, for which the name "algocyan" is proposed, is of a very labile character. It keeps fairly well in aqueous solution (in presence of some ammonium sulfate)

<sup>1</sup> *Handbuch Bioch. Arb. Meth.*, II, p. 691.

if covered with toluene, but slowly fades on exposure to light for some days. Strong mineral acids or alkalies in solution of 1%, or more, decolorize it rapidly, producing a slight white precipitate. The same effect is produced, but more slowly by alcohol. If this be added gradually, there is no perceptible change at 10 or 15%, but when 50% is reached the solution, though still blue, has lost its fluorescence and appears very faintly turbid. The disappearance of the fluorescence seems to coincide with the change of state of the substance from solution to colloidal suspension. Addition of water at this stage does *not* redissolve the substance, and the fluorescence does not reappear. The algocyan is "denatured." Further addition of alcohol causes coagulation of the precipitate; if this be filtered off at once, it may be redissolved in *very* dilute ammonia (about 1 in 1000) but is bleached almost instantly. The neutral solution of unaltered algocyan in water is similarly bleached by ammonia, though a few drops per 1 cc. of 1 in 100  $\text{NH}_4\text{OH}$  may be added without affecting the color or fluorescence. The coloring matter is not carried down by ammonium magnesium phosphate in the solution. The fluorescence is destroyed by dilute acetic acid, indicating that the solution has been changed to a colloidal suspension, as when alcohol is added, but there is a difference in this case, as the fluorescence reappears on adding dilute ammonia till the substance redissolves.

Dilute ferric chloride added cautiously (1 or 2 drops of 1 in 300 solution to each 1 cc. of very deep blue solution of algocyan) precipitates a substance apparently as blue as the original, which redissolves in very dilute ammonia (1 in 1000) to a violet solution of a paler color, from which saturation with ammonium sulfate precipitates a dull blue substance with apparent loss of color.

#### Microkjeldahl Method.

The well known Kjeldahl method for the estimation of nitrogen, as ordinarily carried out, requires the sacrifice of one or two decigrams, or more, of material for each determination. Where only very small quantities of substance are available, satisfactory results can still be obtained by a modification of the details of manipulation. After some experimentation, a method was found which would yield useful information as to the nature of a substance by the analysis of from 5 to 10 mg., and with care should give results accurate to about 1%, or even less, with such minute quantities. While the modifications introduced are only of the nature of details, the great usefulness of a method of obtaining such information, when obliged to work with almost "microchemical" quantities, seems to make it advisable to publish those details here.

For such minute quantities of material, the amount of sulfuric acid taken must be correspondingly reduced, not only to avoid an appreciable error in the correction for the nitrogen in the "blank," but chiefly to re-

duce the volume of the total liquids in the distillation. Half a cubic centimeter of concentrated sulfuric acid was taken each time, measured in a capillary pipet graduated to hundredths, about 0.5 g.  $K_2SO_4$ , and, when necessary to accelerate digestion, one milligram of mercuric oxide. The digestion was performed in a test tube of about one centimeter diameter in the end of which a bulb about 1 inch in diameter had been blown, which gave a space of about 10 cc. for the bursting of the bubbles should the liquid begin to "bump." The tube was used in an inclined position so that the drops should be thrown against the sides, but in spite of this precaution, bumping was the commonest source of trouble in the method and great difficulty was experienced in avoiding errors from this cause. While a slight bumping might occur without introducing serious error, it only needed the loss of a very small drop, where such minute quantities were used, to make the results entirely misleading. However, by the use of a specially small "microburner" in heating, the liquid could usually be made to boil steadily with minute bubbles, or to digest at a temperature a little below its boiling point. For this purpose, a pinhole flame may be used, by burning ordinary gas from a glass capillary about one millimeter in diameter, but besides covering the bulb with soot, the yellow flame was found inferior in another way to that about to be described. To obtain a concentrated heat at a very small point, which is the least likely to cause bumping, and will not boil the acid too rapidly, a blue flame on the principle of the Bunsen burner, not exceeding 6 to 8 millimeters high and 3 or 4 in diameter, was obtained by using a burner, easily made from glass tubing, of the shape and size shown in the sketch. The glass jet A is sealed at B into another piece of tubing BC, in which a slight expansion has been blown just below the point to which the end of the jet A will reach, and in the opposite sides of this expansion, two thin-walled bulbs at D,D. These are then crushed by a smart blow and the edges of the holes rounded in the blow pipe. The opening at C is drawn out to about three millimeters diameter. The size of the air holes at D,D is not very material. They cannot, of course, be regulated, according to the size of the flame, as in an ordinary burner, but for small flames, the inflow of air is nearly self-regulating as the flow of gas alters and there is no danger of the flow "striking back." It was found, how-

Fig. 3.

Fig. 4.

ever, that the flames were often insufficiently oxygenated, however wide the air holes were made, owing to the jet A being too wide, so that the gas did not issue at a high enough velocity to draw in the air required. Care must be taken, therefore, to make this hole small enough, while not so small that the maximum flame, when the gas stopcock is turned full on, is less than that mentioned above. The easiest way to ensure this is to test the jet with full gas pressure before sealing it in: if the yellow flame so obtained is about a centimeter long, the hole is of the right size; if larger, it may be readily contracted by cautious heating of the edges in the blow pipe. A properly adjusted burner gives, with the gas full on, a bright blue flame like that of an ordinary burner which has a slight over-supply of air, about 10 to 12 mm. high; and this can be reduced to half the height without danger of extinction or turning yellowish. In use, the flame is placed close up to the bulb to be heated so that its point just touches the glass, adjusting it carefully beneath the part covered by the acid. If the glass towards the edge of the liquid be directly heated, there is a steadier evolution of bubbles and less tendency to bump, but loss of experiments by cracking of the bulbs is very frequent.

To obviate further the danger of loss by spurting out of minute drops, it was found advisable to place a funnel in the mouth of the tube. An ordinary funnel soon becomes sealed by drops of condensed liquid, which are then spurted out by each sudden evolution of vapor, so a form was designed in which a free passage to the outer air would always remain open, while no drops could possibly be spurted straight through. This consisted in a piece of glass tube just narrow enough to slip easily into the mouth of the test tube with a spherical bulb about 5 mm. wider in diameter blown on the upper end, in which a large round hole, like the opening of a thistle-funnel, has been blown, facing at right angles to the axis of the tube. On the same side, which in use becomes the upper side, a smaller hole not less than 6 or 7 mm. diameter, is blown in the tube at a point half an inch from the bulb and below this the tube is drawn out to a narrower "tail" about half an inch long, bent a little so as to rest against the lower side of the test tube. Any liquid collecting in this funnel runs down into the tail and through the opening in this, back into the test tubes, and although this hole at once becomes stopped by a drop of liquid, gases have always free exit by the opening on the upper side. The larger outer opening being at right angles insures that even if a small drop were accidentally shot through the stem of the funnel, it would strike the side of the bulb and run back. The shape of the funnel allows of its being rinsed out easily, with a few drops of water, outside and in.

Digestion having been effected in the test tube and the acid diluted with not more than 6 or 8 cc. of water, including that used to rinse the funnel, the whole is poured into a distillation flask of special design, and of such

a size that the whole of the ammonia vapor can be driven over with 10 cc. of water or less. This consisted of a small flask with a bulb holding about 25 cc. and a neck about eight inches long, with an inner up-turned tube as a trap, sealed in, where the side tube was attached to the neck. The latter tube is bent down at right angles and has a small oval bulb just below the bend, from which it tapers down to a long, narrow point, which was inserted in a cork fitted into the mouth of a  $6 \times \frac{3}{4}$  in. test tube. This cork was also fitted with an exit tube bent at right angles; a small funnel with a narrow capillary stem reaching down to the bottom of the tube passed through the cork closing the neck of the flask.

Fig. 5.

Having rinsed out the digestion tube into the flask with not more than 5 cc. of water in two small quantities, a measured quantity of strong caustic soda (2.5 cc. of a nearly saturated solution) which had been found to be slightly more than enough to neutralize the acid, was added and the liquid, which did not measure over 20 cc., distilled into an accurately measured quantity of 0.02 *N* hydrochloric acid in the test tube, a rather rapid current of air being drawn through the apparatus during the operation, by connecting the exit tube to an air pump. In five minutes after boiling the ammonia has all passed over, except for negligible traces, so that this stage of the operation is very quick and easy. Even where mercury has been used, in which case sodium sulfide is also added before distilling, the rapid air current prevents bumping, provided the funnel dips to the bottom of the flask. Frothing rarely causes trouble and can be instantly controlled by removing the source of heat, when the cooling effect of the air current is rapidly felt. The effectiveness of this rapid distillation, and of the trap in preventing the carrying over of alkaline spray, was demonstrated by experiments with known quantities of 0.02 *N* ammonium chloride.

The following results, with known substances, will show the degree of accuracy attained when bumping was avoided:

Antipyrine, taken 0.0075 g. Nitrogen found 0.0011 g. equivalent to 15%. Theory requires 14.9%.

$\alpha$ -Naphthylamine, taken 0.0092 g. Nitrogen found 0.00087 g. equivalent to 9.4%. Theory requires 9.8%.

Caffeine, taken 0.0066 g. Nitrogen found 0.0085 g. equivalent to 28.0%. Theory requires 28.9%.

While a certain percentage of results vary 1% or more from the theoretical requirements, indicating that the method of digestion is still capable of improvement, the close agreement of most results, when the very small quantities used are considered, indicates the usefulness of the method as a guide to the composition of an unknown substance, where the quantities available are limited.

### Conclusions.

1. The proportion of protein, fat, moisture and ash has been determined in air-dried *Oscillaria prolifica*.

2. A systematic extraction of the alga has been carried on with various solvents and the approximate proportions extracted have been determined.

3. A new form of extraction apparatus suitable for continuous extraction with volatile solvents of large quantities of material, is here described. This consists of a double siphon, so constructed that an intermittent flow is obtained, as in a Soxhlet's apparatus, allowing of the periodic filling and emptying automatically, of an ordinary flask, between two fixed levels, without a tubulure or aperture in the side of the flask.

4. Crystalline and easily identified characteristic substances were not found in any considerable quantity in the alga. A small quantity of a crystalline magnesium salt of an organic acid (possibly caproic) has been obtained.

5. Saponin of characteristic properties was not obtained in appreciable quantities; a glucoside or polysaccharide having physical properties similar to saponin exists in the plant.

6. The bad smell and taste of the decaying alga appears to be due largely to higher acids of the fatty (butyric) series, some of which were separated: indole or skatole from decomposition of the proteins seems also to be present in traces. The fresh alga contains an aromatic compound soluble in petroleum spirit which causes a characteristic odor.

7. The spectra have been determined of various coloring matters from the alga, a "chlorophyll" similar to that of the higher plants and a blue substance soluble in water and in glycerol, with an intense red fluorescence, having properties which indicate that it is either associated with and carried down by the proteins in solution, or itself has similar precipitation properties. This substance, which is believed to be new, and may be allied chemically to the chlorophyll of the alga, has been named "algcyan."

8. The chief carbohydrate in the plant is a pectin-like substance insoluble in water with a great power of forming jelly on heating. It is hydrolyzed with remarkable slowness by boiling with 5% sulfuric acid; the examination of the products indicated the presence of a nonreducing

substance with a high positive rotation, and a reducing sugar with smaller rotation (eventually becoming zero or slightly negative) formed from this by further hydrolysis. A small quantity of a phenyl hydrazine compound was obtained which in the pure state melted at  $217^{\circ}$  (corrected) and contained about 11% of nitrogen: this can not be identified with any known compound.

9. A modification of the details of manipulation of the Kjeldahl method of nitrogen determination has been worked out, allowing of approximate analyses of as little as five to ten milligrams of material, containing about one milligram or less of nitrogen.

Boston, Mass.

## THE POISONOUS PRINCIPLE OF POISON OAK

(*Rhus diversiloba*, T. and G.).

By JAMES B. MCNAIR.

Received December 13, 1915.

**Botanical Similarity between Poison Oak (*Rhus diversiloba*) and Poison Ivy (*Rhus toxicodendron*).** — The difference between *Rhus diversiloba* and *Rhus toxicodendron* is so small that their proper classification forms a bone of contention between botanists. Those botanists that believe in innumerable species are in favor of their separation, while the more conservative are opposed to it. Greene,<sup>1</sup> considers *Rhus diversiloba* "a peculiar type of *toxicodendron* belonging exclusively to the Pacific coast." Engler<sup>2</sup> believes *diversiloba* a sub-species of *toxicodendron*. The only botanical ground for the separation of the two into different species is a slight difference in the shape of their leaflets.<sup>3</sup>

**Is the Poison a Glucoside of Rhamnose, Gallic Acid and Fisetin?—** As far as is known to the writer no work has been published on the chemistry of the poisonous principle of poison oak (*Rhus diversiloba* T. and G.). Because of the very close botanical relationship existing between poison oak and poison ivy (*Rhus toxicodendron*, L.) and because of their identical pharmacological action it has always been held among the medical profession, as well as among botanists, that the poisons were identical. Not only are they similar in pharmacological action, but they are also similar in solubility, rapid oxidation, etc.

In seeking to find out the constitution of the poisonous compound of poison oak the work done on its very closely related plant has been investigated. Perhaps the most recent work is that of Syme, 1906,<sup>4</sup>

<sup>3</sup> Gray, "Synoptical Flora" (1895-7), Vol. 1, Pt. 1, Fasc. 1-2, p. 382-383.

<sup>4</sup> W. A. Syme, "Some Constituents of Poison Ivy Plant," Johns Hopkins University Dissertation, 1906; Acree and Syme, *Am. Chem. J.*, 36, 303, 316 (1906).

who claims to have found upon a hydrolysis of the poison of *Rhus toxicodendron*, rhamnose, gallic acid and fisetin.

In an attempt to secure on hydrolysis of the poisonous principle of poison oak the same constituents as Syme obtained from poison ivy the writer was unsuccessful. Therefore, it must be concluded that the poison of *Rhus diversiloba* is not a glucoside of rhamnose, gallic acid and fisetin.

While we have not repeated the work on the plant Syme experimented with, it seems strange that such closely related plants should have such widely different poisonous principles. It is true that there is often a slight change in the chemical constitution of glucosides, oils, nitrogenous bases, etc., between plants of the same botanical genus, but it is, indeed, an exception where a wide variance occurs as the results of these experiments would indicate.<sup>1</sup>

Such a difference in the chemical nature of the poisons could hardly be laid to a difference in climate or soil. Poison ivy is found all over Eastern United States as well as in Washington and Oregon. Poison oak is found from the Gulf of California to the Canadian border. Who shall say that it does not endure at least as rigid a climate and surely as mild a one as poison ivy?

Fisetin, gallic acid, and rhamnose, the constituents of Syme's glucoside are found in large quantities in two plants of the botanical genus to which both poison ivy and poison oak belong, viz., *Rhus cotinus*, L.<sup>2</sup> and *Rhus rhodanthema*.<sup>3</sup> It might be supposed from Syme's observations that these species would be poisonous. As a matter of fact, however, neither of these species is poisonous.

*Rhus cotinus* yielded, when analyzed in 1886 by Schmid,<sup>2</sup> a glucoside on water extraction which was called "glycosidgerbsäure des Fisetins" or Fustin tannid. This substance gave, on hydrolysis with alkalis or mineral acids, the same substances which Syme's glucoside contained, viz., fisetin, rhamnose, and gallic acid.

While it cannot be positively denied that some poisonous glucoside may exist which contains fisetin, rhamnose, and gallic acid, yet so far as known there has been no corroboration of Syme's conclusion. All the evidence at hand points towards a nontoxicity of a glucoside of fisetin, gallic acid and rhamnose.

In repeating the work of Syme the writer used gasoline as an extractive material in preference to ether which Syme used. This selection was made because the writer realized that gasoline did not appreciably dissolve rhamnose, gallic acid, tannin, or fisetin, whereas ether does act as a solvent for gallic acid, tannin,<sup>4</sup> and fisetin when combined with

<sup>1</sup> Pictet and Biddle, "The Vegetable Alkaloids," p. 114-115.

<sup>2</sup> Schmid, *Ber.*, 79, 1734 (1886).

<sup>3</sup> Perkin, *J. Chem. Soc.*, 71, 1194 (1897).

<sup>4</sup> Beilstein, *Organische Chemie*.

rhamnose.<sup>1</sup> Besides these things ether dissolves many other interfering substances, e. g., chlorophyl,<sup>2</sup> which gasoline does not.

While both of us worked with a "poisonous tar, wax, or gum," yet there is reason to believe that ours was the purer product. It cannot be denied at present that there may be a poisonous glucoside of fisetin, rhamnose, and gallic acid, but there is certainly strong presumptive evidence that such is not the case. There is not sufficient evidence that the poisonous substance which Syme attempted to decompose was not a complex containing the poisonous body and one or more nontoxic glucosides in addition. These may consist of some combination of fisetin, rhamnose, and gallic acid.

We would suggest, therefore, that the work with *Rhus toxicodendron* be repeated for substantiation and a synthesis be made of the pure poison or poisons. For it seems strange indeed that such closely related plants should have such different poisons.

### Experimental Data.

An attempt to verify the results of Syme's hydrolysis was made by the author with the poison of *Rhus diversiloba*.

The poisonous principle in the following experiment was obtained by extracting *chips* of *limbs* in a Soxhlet apparatus with 86° Baumé gasoline. In other experiments the *leaves* have been used and similar results obtained. The gasoline was evaporated and the black residue pulverized in a glass mortar. The powdered material was placed with two liters of distilled water in a tall glass cylinder. The black substance was insoluble in water and sank to the bottom of the cylinder. It was thoroughly shaken at least once a day for a week, after which time the aqueous portion was decanted. Two liters of fresh distilled water were now added and the shaking process repeated for another week. At the expiration of this time the aqueous liquid was decanted from about 25 g. of the black material, and the liquid was evaporated to dryness. The residue, very small—about 3 mg. per liter—represented the amount of water-soluble constituents in the black material.

The black material was repeatedly extracted with 95% alcohol. The first portions of the alcoholic extract were colored light brownish yellow. The later portions of the extract were light yellow, indicating that the chromatic alcohol soluble material had been nearly all extracted. This poisonous alcoholic extract, which amounted to about 800 cc., was heated on the water bath during working hours for two and one-half days with a solution of 2 g. of concentrated sulfuric acid in 100 cc. water—to hydrolyze the alcohol-soluble material.

<sup>1</sup> Schmid, *Ber.*, 79, 1734 (1886).

<sup>2</sup> Syme, *Loc. cit.*

The alcohol was driven off of the solution at the end of the period of treatment. The colors of the solution were as follows:

Color of alcoholic extract, light brownish yellow; color after addition of acid solution, the same; color of solution after driving off alcohol, the same. When the alcohol was driven off there remained, besides the aqueous solution, a quantity of black tar-like material, insoluble in water.

An alcoholic solution of the tar-like material was extremely poisonous, while the aqueous solution was found to be nonpoisonous when applied to tender skin. *In the aqueous solution* should be Syme's so-called hydrolysis products of the poison ivy, *viz.*, fisetin, gallic acid, and rhamnose, as each of these materials is easily soluble in water.

#### Reactions of the Aqueous Solution.

**Rhamnose**, or any other reducing sugar, was not present for the following reasons:

A portion of the solution which had been neutralized to litmus with a sodium carbonate solution gave a slight turbidity when treated with Fehling's solution. The slightest perceptible amount of copper oxide was precipitated, not enough to be a decisive test for reducing sugars.

A portion of the neutralized and also of the unneutralized solution tested with  $\alpha$ -naphthol<sup>1</sup> gave a negative test for carbohydrates. It was found that when the solution was passed through an ordinary filter paper the test gave positive results; this was due to carbohydrates from the paper.

**Gallic acid** was not present for the following reasons:

When a portion of the unneutralized solution was treated with ferric chloride solution a light brown color was produced, no precipitate. The color was somewhat deeper than the original solution before treatment. When a drop of sodium carbonate solution was added, a precipitate of ferric hydroxide was formed, the solution filtered from the mass was nearly colorless, being slightly yellowish.

**Fisetin** was not present, for when a portion of the aqueous solution was shaken with ethyl acetate no coloring matter was extracted from the solution.

#### Comparison of this Attempted Hydrolysis with the Work of Syme.

No similarly colored solution was formed during the hydrolysis as was mentioned in his work.

No tests indicating gallic acid were obtained by means of ferric chloride as is to be found in the dissertation.

Positive tests for rhamnose or reducing sugars with  $\alpha$ -naphthol and Fehling's solution were not obtained. Especial care was taken in the filtrations throughout to use glass wool instead of filter paper in order that dissolved carbohydrates from the paper would not interfere with the test for rhamnose.

<sup>1</sup> Browne, "Handbook of Sugar Analysis," p. 341.

The hydrolysis did not liberate fisetin. This was indicated by the fact that ethyl acetate shaken with the aqueous solution did not extract coloring matter from the solution.

### No Optical Activity.

A gasoline solution of the poison, the aqueous solution of possible hydrolytic products, as well as an ethyl acetate solution of the poisonous hydrolytic residue, exhibited *no* evidences of optical activity when observed through a decimeter tube in a triple field saccharimeter.<sup>1</sup> While this does not positively prove the absence of an asymmetric carbon atom, or rhamnose in the poison, it furnishes strong presumptive evidences in that direction.

From the evidence presented above it is concluded that the poison in *Rhus diversiloba* cannot be hydrolyzed by means of acid into the compounds, rhamnose, gallic acid, and fisetin.

### Summary.

1. *Rhus diversiloba* and *Rhus toxicodendron* are very similar plants; their only botanical difference lies in a slight difference in the shape of their leaflets.

2. The poisonous principle of *Rhus diversiloba* is not a glucoside of rhamnose, fisetin and gallic acid.

3. Syme's conclusion that the poison of *Rhus toxicodendron* is a glucoside of fisetin, rhamnose, and gallic acid should be repeated for substantiation for:

(a) It seems strange that two such closely related plants botanically should have such widely different poisons chemically.

(b) All three of the so-called constituents of the poison are found in two nonpoisonous species of *Rhus*.

(c) The natural glucoside of fisetin, rhamnose and gallic acid is non-toxic.

(d) There is not sufficient evidence that a poisonous substance which Syme attempted to decompose was not a complex containing a poisonous body to one or more nontoxic glucosides in addition.

I am indebted to Professors H. C. Biddle and T. Brailsford Robertson for their advice throughout the investigation.

## ON THE CONSTITUENTS OF POISON IVY (*Rhus toxicodendron*).

BY S. F. ACREE.

Received March 22, 1916.

The interesting article presented in the preceding pages was kindly referred to me by the author for the publication of a simultaneous note. As Dr. Syme died several years ago and his note-books are not available,

<sup>1</sup> Made by Hantz Schmidt Haensch, Berlin, Germany.

and the busy life makes us forget the details of work finished ten years before, the writer can give only a general statement regarding the preceding note by McNair. This article has been referred to him.

Two points in McNair's paper will be discussed: Namely, (1) the logic and, (2) the facts, imperfections in either of which lead, save by accident, to wrong conclusions. Syme had considerable knowledge of this difficult plant work and was peculiarly adapted to this kind of problem. He worked on the *ether extract* of the *leaves and flowers* of *Rhus toxicodendron*, whereas McNair worked on the *gasoline extract* of the *limbs* of *another species*, *Rhus diversiloba*, and, as *might* be expected, secured *different results*. He therefore concluded that *Syme's work* is wrong. The only other comment to be added is that McNair may not have given sufficient weight to the well-known fact that the botanical differences in species may often be detected only with difficulty whereas the chemical differences may differ widely. This phase of the work has been discussed a number of times, especially in an illuminating article by Schorger<sup>1</sup> to whom I am indebted for the following résumé.

It is well known that the same plant yields very different volatile oils in different localities having different soils, moisture conditions, and climates. The Lavender plant (*Lavandula vera*) of France gives an oil containing 40 to 42% of esters, whereas in England the same species gives an oil whose ester content never exceeds 10%. The fennel oil produced in Saxony, Galicia, and Moravia, contains fenchone, which is entirely absent in the Macedonian product. Clover<sup>2</sup> and Bacon<sup>3</sup> showed that different trees of the species *Canarium luzonicum* A. Gray gave resins which yielded oils consisting either of pure terpinene, limonene, or phellandrene. Bourquelot and Fichtenholz<sup>4</sup> found the glucoside arbutine in the leaves of *Pyrus communis* but none could be detected in the leaves of *Cydonia vulgaris* Pers., *Malus communis* Link., *Sorbus aucuparia* L., or *S. torminalis* Crantz, all of which were formerly classed as *Pyrus*.

Another very interesting case is a set of the oils obtained by Schorger from Jeffrey pine, western yellow pine, and the "cross variety" pine, which resemble each other so closely that it is difficult to tell them apart by botanical methods. The oil from the Jeffrey pine boils at about 98° and contains 95% of heptane. The oil from the typical western yellow pine (*P. ponderosa*) boils at 164° and contains no heptane and yields about 65% of  $\beta$ -pinene. The "cross variety" of the western yellow pine boils at 165° and contains  $\beta$ -pinene, and limonene in some cases. The

<sup>1</sup> "Chemistry as an Aid in the Identification of Species," *Proc. Soc. Am. Forest.*, **11**, 33 (1916).

<sup>2</sup> *Phil. J. Sci.*, **2A**, 1 (1907).

<sup>3</sup> *Ibid.*, **4A**, 93 (1909).

<sup>4</sup> *J. pharm. chim.*, **VII**, 3, 5 (1911).

"bastard" pine boils at  $156^{\circ}$  and contains no heptane but about 65% of  $\alpha$ -pinene. The western yellow pine (*P. ponderosa scopulorum*) of Arizona boils at  $157^{\circ}$  and contains no heptane but about 65% of  $\alpha$ -pinene. The optical rotations of these substances vary in a similar way.

Schorger has discovered some other facts of great interest in this connection. The oleoresin from both *P. jeffreyi* and *P. sabiniana*<sup>1</sup> give heptane on distillation. The oil distilled from the needles and twigs of *P. sabiniana* was found to contain only 3% of heptane, the remainder consisting of *terpenes*.<sup>2</sup> This small amount of heptane may, doubtless, be that which occurred in the woody portion of the twigs. *Many other cases are known in which the leaves contain compounds not found in the bodywood, bark, or roots of the same tree, and vice versa.*

This observation and the results given above show beyond question that the phytochemical processes occurring in the needles and in the wood of these conifers are entirely different. This being the case it would be dangerous to assume that the poison occurring in the *leaves and flowers* of *Rhus toxicodendron* should be found in the *bodywood* of this plant and certainly it is entirely inadmissible to assume that this same poison, or the same nontoxic constituents, should be found in the *limbs* of an entirely different species, *Rhus diversiloba*.

McNair's discussion of the solubilities of complex glucosides and their relation to the solubilities of the components, as well as his reasoning on the relation of the toxicity of a complex organic compound to the toxicity of the constituents, or *vice versa*, will find many opponents among the pharmacologists and plant chemists. Any good book, such as Fraenkel's "Arzneimittelsynthese," gives numberless illustrations to show that the general relationships assumed by McNair can not hold. Derivatives of saccharin lose the sweet taste. The local anesthetic cocaine is made up of a combination of ecgonine, benzoic acid and methyl alcohol, no one of which has the same action as the cocaine. The examples could be multiplied indefinitely, as I am assured by my friends, Loevenhart and Kremers.

Coming to the discussion of (2) Syme's *facts*, we note again that because McNair *failed* to find gallic acid, fisetin and rhamnose as free or combined constituents of the *gasoline extract* of the *limbs* of *Rhus diversiloba* he concludes that Syme could not have found them in the *ether extract* of the *leaves and flowers* of another species *Rhus toxicodendron*.

McNair criticizes Syme's work on the hydrolysis products of the poisonous tar or wax after simply making a few negative color tests. After noting that McNair himself did not isolate anything more crystalline than a "dark liquid mystery," which still remains so, let us review

<sup>1</sup> Bull. 119 Forest Service; *J. Ind. Eng. Chem.*, 5, 971 (1913).

<sup>2</sup> *J. Ind. Eng. Chem.*, 7, 24 (1915).

what Syme actually obtained in the crystalline state. From the aqueous extract of the total poisonous tar Syme obtained crystalline potassium, barium and sodium salts and crystalline gallic acid, melting point  $230^{\circ}$ , and converted it into the crystalline ethyl ester, which melted at  $156-9^{\circ}$ , whether alone or mixed with the ethyl ester prepared from Kahlbaum's gallic acid. He then subjected the gallic acid to the characteristic color and other tests discussed in his dissertation. The most concentrated "poisonous tar, gum or wax," was called the "poison" for brevity, but was obviously never considered to be "crystalline" and pure. This substance, on hydrolysis, gave the same characteristic color and other tests for gallic acid, but the amount of "poison" available was too small to attempt to isolate crystals and it was used chiefly for the more valuable toxicity and other tests.

Turning to the dyestuff, fisetin, which McNair could not find in another species, we note that Dr. Syme did isolate crystalline fisetin from the total tar, studied its color reactions and even decomposed two grams of it into phloroglucinol and protocathechuic acid. Syme was already familiar with fisetin and I believe had samples for comparison. As stated above, the amount of the most concentrated "poison" was too small to allow Syme to isolate crystalline fisetin from its hydrolysis products, but he obtained the same characteristic color and other tests found for his crystalline fisetin.

Coming to rhamnose we found that Syme discussed fully the difficulties of obtaining this sugar, as indeed most sugars, in the crystalline state. He had to be content, therefore, with characteristic color and other tests worked out for crystalline rhamnose, including of course the conversion into methyl furfural.<sup>1</sup> Of course a number of the methyl pentoses discovered since that time give a number of similar tests.

As stated above, the "poison" was a tar, wax or gum, and Warren believes that this "poison" may have been a complex mixture containing the pure poison or poisons and one or more nontoxic glucosides which can yield the gallic acid, fisetin and rhamnose. Warren and McNair then agree with Syme's Paragraph 3, p. 563, *J. Biol. Chem.*, Vol. II. "In this experiment, gallic acid and fisetin and probably sugar were formed by decomposition of the poisonous gum with acetic acid, the acid found in the plant by Pfaff. The presence of free gallic acid, fisetin, and rhamnose in the plant can be explained by the natural *hydrolysis of a complex gum or tar or a constituent thereof* (italics new). The poisonous property is lost in the general rearrangement which takes place during hydrolysis." This conclusion was so obvious that it never occurred to Syme or the writer that any other conclusion could be drawn from the work. Any organic chemist knows that such a tar is a mixture, and Syme never for a

<sup>1</sup> Dissertation, pages 23-25.

moment desired to word his articles in such a way that the reader would be left under the impression that a "pure poison" could be obtained in this way. The whole object of this work was to isolate the poison in some fraction or fractions, and study these fractions with the view (1) of measuring the toxicity and finding a method ( $\text{KMnO}_4$ ) for curing the wounds, and with the aims (2) of isolating and synthesizing the real poison or poisons. The work was discontinued because the very small amount of "poison" in the \$100 worth of "total poison or tar" available made the further prosecution of the problem appear too expensive. We should indeed be glad to see anyone with the necessary funds continue this research and synthesize the pure poison or poisons. Success in this direction would mean much toward the solution of a problem which causes a great deal of human suffering.

### Summary.

1. McNair's reasoning that the limbs of *Rhus diversiloba* should contain the same toxic and nontoxic constituents found in the leaves and flowers of another species, *Rhus toxicodendron*, in another locality and climate is against all the well-known evidence because:

(a) The botanical differences in species may often be detected only with difficulty while the chemical constituents may vary widely.

(b) The same species gives different substances in different localities and climates.

(c) The constituents found in the leaves of a given species are generally *not* identical with those found in the limbs of the same plant, much less of a different species under different conditions.

2. It is highly probable that Syme's "purified poisonous tar, gum or wax" was a mixture of toxic and nontoxic materials. Syme's "purified" the material as far as possible and when it gave out suspended the work on account of the expense. Although his description of the "purified poisonous tar, gum, or wax" and its reactions was in some places perhaps confusing, Syme did not believe that his "purified poison" was not a mixture. It is highly desirable to have the studies on all these toxic plants continued.

## THE NONPROTEIN NITROGENOUS CONSTITUENTS OF FEEDINGSTUFFS.

BY H. S. GRINDLEY AND H. C. ECKSTEIN.

Received May 25, 1916.

When the Van Slyke method for the determination of the chemical groups characteristic of the different amino acids of proteins was first

proposed as a method for the estimation of the free and the combined amino acids and the free and the combined amides of feedingstuffs,<sup>1</sup> it was realized that it would be necessary, in order to establish the accuracy of the method, to demonstrate that the nonprotein nitrogenous constituents of feedingstuffs do not lead to inaccurate experimental results or to results that falsify the interpretation of the experimental data so obtained. The investigation here reported was undertaken as a necessary step in this direction. The preliminary results of this work were reported at the New Orleans meeting of this Society.<sup>2</sup> Since that time Hart and Bentley<sup>3</sup> have published a paper relating to this same subject.

Briefly stated, the method finally adopted for the work here reported was as follows:

Ten to twenty-five grams of the feedingstuff, placed upon a four-inch Büchner funnel, were washed repeatedly with cold ammonia-free water until the filtrate measured about 2400 cc. The extract was diluted to 2500 cc.

(a) **The Total Soluble Nitrogen** was determined in 200 cc. portions of the extract in duplicate.

(b) **The Free Ammonia** was determined in a 500 cc. portion of the extract by the Van Slyke vacuum method.

The native-proteins were separated in a 1250 cc. portion of this extract by heating it to boiling and by adding, drop by drop, while constantly stirring 7.5 cc. of colloidal ferric hydroxide<sup>4</sup> (containing 5% of  $\text{Fe}_2\text{O}_3$ ). The solution was then boiled for one minute and 1.0 cc. of a solution of crystallized magnesium sulfate (made by dissolving  $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$  in an equal weight of water), was added to coagulate the excess of colloidal ferric hydroxide. The solution was again boiled for one minute. After standing overnight, the solution was filtered through folded filters and the precipitate was thoroughly washed with hot water. The filtrate and washings after being diluted to 1500 cc. were used for the following determinations:

(c) **The Total Nitrogen** not precipitated by the colloidal ferric hydroxide was determined in duplicate in 200 cc. portions.

(d) **The Free Ammonia** was determined in one portion of 500 cc. by the Van Slyke vacuum method.

(e) **The Free Amino-Acid Nitrogen** was determined by slightly acidifying the residual mixture left in the distilling flask from the above determination in (d) with hydrochloric acid, filtering and washing. The filtrate and washings were evaporated in a porcelain dish on the steam

<sup>1</sup> THIS JOURNAL, 37, 1778 (1915); 37, 2762 (1915).

<sup>2</sup> See *Science*, 42, 70 (1915) for abstract of paper.

<sup>3</sup> *J. Biol. Chem.*, 22, 477 (1915).

<sup>4</sup> Merck's.

bath to about 15 cc. The concentrated solution was washed into a 25 cc. measuring flask and diluted to the mark. The amino-acid nitrogen was determined in duplicate in 10 cc. portions of this solution by the Van Slyke nitrous acid method.

(f) **The Free and Combined Acid-Amide Nitrogen** were determined in a 500 cc. portion of the solution by adding enough of concentrated hydrochloric acid to give a concentration of 20% and then boiling under a reflux condenser for 12 hours. The excess of hydrochloric acid was removed by evaporation *in vacuo* and the ammonia determined by the Van Slyke vacuum method. One-half of the weight of the free ammonia nitrogen determined above in (b) subtracted from the weight of the ammonia nitrogen obtained in this determination gave the weight of the free and combined acid-amide nitrogen in one-half the quantity of the feedingstuff originally taken for the analysis. The free ammonia nitrogen as determined in the original water extract was considered more accurate than the corresponding determination in the filtrate from the colloidal iron precipitation, as the heating of the solution during the latter precipitation, clearly hydrolyzed, in part, the free acid amides present with the liberation of ammonia.

(g) **The Humin Nitrogen**, which was formed in the above determination by boiling the aqueous extract of the feedingstuffs with 20% hydrochloric acid for 12 hours, was filtered off and washed as per the Van Slyke method. The nitrogen in the humin precipitate was determined by the Kjeldahl method.

(h) **The Combined Amino-Acid Nitrogen** was determined by slightly acidifying the filtrate and washings from the above determination in (g) and then evaporating the resulting solution in a porcelain dish on the steam bath to about 30 cc. The concentrated solution was washed into a 50 cc. measuring flask and diluted to the mark. The amino-acid nitrogen was determined in duplicate in 10 cc. portions of this solution by the Van Slyke nitrous acid method. The free amino-acid nitrogen determined above in (e) subtracted from the free and combined amino-acid nitrogen obtained in this determination gave the combined amino-acid nitrogen.

(i) **The Residual Soluble Nitrogen**, which did not respond to any of the above tests, was obtained by subtracting the sum of one-half of the free ammonia nitrogen obtained in (b), the free amino-acid nitrogen obtained in (e), the free and combined acid-amide nitrogen obtained in (f), the humin nitrogen obtained in (g), and the combined amino-acid nitrogen obtained in (h) from the total nitrogen not precipitated by colloidal iron hydroxide obtained in (c).

It is possible that some of the humin nitrogen has its origin in the free amino-acid nitrogen. If this is true, then the residual soluble nitrogen

would necessarily be increased to an equivalent extent. At present, it is impossible to determine how much of the humin nitrogen comes from the free amino-acid nitrogen, and how much of it comes from the combined amino-acid nitrogen.

Much difficulty was experienced in obtaining a complete extraction of the food material with cold water. By the method described above the total nitrogen not precipitated by colloidal ferric hydroxide in a second extract following the first, and measuring 1000 cc., was reduced to less than 0.6% of the total nitrogen present in the alfalfa hay; to less than 0.5% of the total nitrogen of timothy hay; to less than 0.3% of the total nitrogen of the corn; and to less than 0.07% of the total nitrogen of the blood meal.

The use of colloidal ferric hydroxide for the separation of the proteins from the nonproteins was suggested by the recent use of this reagent for the separation of proteins from blood, milk, and partially digested proteins by Wolff,<sup>1</sup> Hill,<sup>2</sup> and Van Slyke,<sup>3</sup> *et al.*, Van Slyke, Vinograd-Villchur and Losee<sup>3</sup> say: "In experiments on Witte peptone and partially digested protein to be published later we have found, furthermore, that colloidal ferric hydrate not only lets all the amino acids go through

into the filtrate, but that it also precipitates none of the intermediary products up to the albumoses, and none of these except some of complexity but little below that of the original proteins (proportion of amino nitrogen was but 6 to 7% of the total in the precipitated albumoses). As the precipitation of the native proteins themselves is complete, colloidal ferric hydrate appears especially well adapted to our purpose."

The character of the results obtained by the application of this method to the examination of a few feedingstuffs is apparent from the data given in Tables I, II, and III. In Table I, the nonprotein nitrogenous constituents of feedingstuffs are given expressed in per cent. of the total nitrogen of the feedingstuff. In Table II, the nonprotein nitrogenous constituents are expressed in per cent. of the feedingstuff. In Table III, the non-

protein nitrogenous constituents are expressed in per cent. of the total soluble nitrogen not precipitated by colloidal ferric hydroxide.

It is apparent that this method of the determination of the nonprotein nitrogenous constituents of feedingstuffs gives a fairly complete picture of the different forms of nitrogen represented in the so-called nonprotein nitrogenous constituents.

It is also apparent that the nonprotein nitrogenous constituents consist largely of the forms of nitrogen that result from the decomposition of proteins by hydrolysis. In other words, the sum of the amide nitrogen, the humin nitrogen, the free amino-acid nitrogen, the combined amino-acid nitrogen, and the free and combined acid-amide nitrogen represented in the nonprotein nitrogenous constituents form from 80% in the case of alfalfa hay to 94% in case of blood meal, of the nonprotein nitrogen. Further, it is probable that at least 50% of the residual soluble nitrogen not precipitated by colloidal iron represents the nonamino nitrogen present in the free and combined amino acids determined.

It is impossible at present to tell definitely what the remaining 3 to 10% of residual soluble nitrogen, which does not respond to any of the tests here applied, represents. However, it seems quite evident that only a small part, if any, of the nonprotein nitrogenous constituents of foods and feedingstuffs can in any way interfere with the application of the Van Slyke method for the determination of the chemical groups characteristic of the different amino acids of protein to the estimation of the free and combined amino acids and amides of feedingstuffs.

It is also evident that the so-called amide nitrogen of feedingstuffs is largely composed of free amino acids and peptide linkings. The nitrogen in these latter forms including the humin nitrogen constitute from 53 to 63% of the water-soluble nitrogen not precipitated by colloidal ferric hydroxide. Hart and Bentley<sup>1</sup> by the use of their method, which differs entirely from the method we here propose, reported 50 to 70% of the water-soluble nitrogen of immature and mature plants, that was not precipitated by boiling the slightly acidified extracts, as free amino acids and peptide linkings.

The free and combined acid-amide nitrogen varied from 17.11 to 25.67% of the soluble nitrogen not precipitated by colloidal ferric hydroxide. Hart and Bentley found the "free acid-amide nitrogen" by their method to be relatively small, seldom exceeding 20% of the water-soluble nitrogen, and more often being below 10%. Our results which represent the free and the combined acid-amide nitrogen are not directly comparable with those of Hart and Bentley which they considered to represent only the free acid-amide nitrogen. However, it does not seem probable, that the results they obtained for this determination represent merely free acid-

<sup>1</sup> *J. Biol. Chem.*, 22, 477 (1915).

amide nitrogen, for it is a well-known fact that proteins and peptide linkings very readily yield ammonia when boiled with 20% hydrochloric acid.

In the work here reported the free ammonia nitrogen varied from 6.33 to 12.04% of the water-soluble nitrogen not precipitated by colloidal iron. Hart and Bentley found by their method that the free ammonia nitrogen of immature and mature plants rarely exceeded 5% of the water-soluble nitrogen, and in some instances was wholly absent. Their low results for ammonia were probably due to the direct extraction of the food materials with *hot* water. We have confirmed the results of Hart and Bentley that an extract of alfalfa hay prepared with boiling water contains no free ammonia, or at least only a slight trace. On the other hand, as shown in the Table III, a cold water extract of alfalfa hay contained 6.33% of its total soluble nitrogen not precipitated by colloidal iron, in the form of free ammonia. Further, an extract of alfalfa hay prepared by hot water slightly acidified (0.185% hydrochloric acid), contained 4.44% of its total soluble nitrogen, not precipitated by colloidal iron, as free ammonia. A water extract of alfalfa hay is distinctly alkaline to litmus paper.

Further studies to determine the amount and the nature of the nonprotein nitrogenous constituents of feedingstuffs are now under way in this laboratory.

URBANA, ILL.

## THE ISOMERIC PENTACETATES OF GLUCOSAMINE AND OF CHONDROSAMINE.<sup>1</sup>

BY C. S. HUDSON AND J. K. DALE.

Received May 22, 1916.

Two isomeric pentacetyl derivatives of glucosamine have been described by Lobry de Bruyn and Van Ekenstein.<sup>2</sup> If these compounds have the isomeric structures,

<sup>1</sup> Contribution from the Carbohydrate Laboratory, Bureau of Chemistry, United States Department of Agriculture.

<sup>2</sup> *Rev. trav. chim.*, 18, 83 (1899).

the molecular rotations of the substances may be expressed by the quantity  $(A + B)$  for one form and  $(-A + B)$  for the other, in accordance with considerations advanced by one of us,<sup>1</sup> and more recently developed in connection with the acetyl derivatives of the sugars.<sup>2</sup> The quantity  $A$  represents the rotation which is due to the end asymmetric carbon atom and  $B$  denotes the rotation due to the remainder of the molecule. In a similar manner the molecular rotations of the alpha and beta forms of glucose pentacetate,

may be written  $(A + B')$  and  $(-A + B')$  where  $B'$  is of different value from  $B$  on account of the dissimilarity of the glucose and glucosamine chains. The difference between these values for the alpha and beta glucosamine pentacetates is  $2A$  and the corresponding difference for the glucose pentacetates is also  $2A$ . The deduction is drawn that the difference between the molecular rotations of the glucosamine pentacetates is equal to that of the glucose pentacetates. Lobry de Bruyn and Van Ekenstein found the specific rotation in chloroform solution of the more soluble glucosamine pentacetate to be  $+86.5^\circ$  and the less soluble form to be optically inactive, thus a molecular<sup>3</sup> rotation difference of  $+33,600$ . The similar difference for the glucose pentacetates we have found to be  $+38,100$ .<sup>4</sup> The disagreement amounts to 4,500 or about  $11.5^\circ$  in specific rotation. This considerable divergence suggested to us that the specific rotation of one or both of the glucosamine pentacetates might be in error due to an incomplete separation of the isomers. Accordingly, the preparation and purification of these compounds was undertaken for a re-determination of their specific rotations. We have found for the more soluble glucosamine pentacetate, which we will call alpha because it is more dextrorotatory than the other isomer,  $[\alpha]_D^{20} = +93.2^\circ$ , instead of  $+86.5^\circ$ , and for the less soluble pentacetate, the beta form,  $[\alpha]_D^{20} = +1.2^\circ$ , instead of optical inactivity. These values correspond to a molecular rotation difference of  $+35,800$  which is 2,300 less than the difference for the glucose pentacetates, a disagreement of about  $6^\circ$  in specific rotation. Although this difference is more than the uncertainty of the mea-

<sup>1</sup> Hudson, *THIS JOURNAL*, **31**, 66 (1909).

<sup>2</sup> *Ibid.*, **37**, 1264, 1270, 1276, 1280, 1589, 1591, 2748 (1915).

<sup>3</sup> The molecular weights used are 389 for glucosamine pentacetate and 390 for glucose pentacetate.

<sup>4</sup> *THIS JOURNAL*, **37**, 1264 (1915).

surements, on the other hand, the agreement with the theory is close enough to justify the nomenclature we have adopted for the two substances.<sup>1</sup>

**The Isomeric Pentacetates of Chondrosamine.**—Chondrosamine hydrochloride, prepared by Levene and LaForge,<sup>2</sup> is isomeric with glucosamine hydrochloride. The existence of two pentacetates of glucosamine suggested the existence of two similar derivatives of chondrosamine. Both of these compounds have been prepared as described in detail farther on and their specific rotations in chloroform carefully measured. Since chondrosamine hydrochloride has been shown to be the hydrochloric acid salt of either *l*-allose- or *l*-altrose-amine,<sup>3</sup> the structures of its pentacetyl derivatives will be, for one form,

for the other. The end asymmetrical carbon atom in these compounds has the same configuration as in glucosamine pentacetate and glucose pentacetate, but the remainder of the molecule is different, hence the molecular rotations of the alpha and beta forms may be written  $(-A + B'')$  and  $(A + B'')$ .<sup>4</sup> The difference is  $-2A$ , identical with the quantity that was found for the glucosamine pentacetates and the glucose pentacetates, but opposite in sign, hence the difference of the molecular rotations of the chondrosamine pentacetates should be equal and opposite to that of the glucosamine pentacetates and of the glucose pentacetates. In Table I is given the specific rotation of each of these compounds with the corresponding molecular rotation and the differences in molecular rotation.

<sup>1</sup> Lobry de Bruyn and Van Ekenstein named these compounds in the opposite sense, the less soluble form, alpha, and the more soluble form, beta, their reason seeming to be that the less soluble isomer was obtained first.

<sup>2</sup> *J. Biol. Chem.*, **18**, 126 (1914).

<sup>3</sup> Levene and LaForge, *J. Biol. Chem.*, **20**, 433 (1915).

<sup>4</sup> Since chondrosamine is genetically related to *l*-glucose, the lower rotating pentacetyl derivative is to be named the alpha form and the higher rotating isomer the beta. See *THIS JOURNAL*, **31**, 66 (1909).

TABLE I.

Substance.	$[\alpha]_D^{20}$ <sup>1</sup>	Molecular rotation.	Difference.
$\alpha$ -Glucosamine pentacetate.....	+ 93.5°	+36,400 = +A + B	35,930 = 2A
$\beta$ -Glucosamine pentacetate.....	+ 1.2°	+ 470 = -A + B	
$\alpha$ -Chondrosamine pentacetate.....	+ 10.5°	+ 4,100 = -A + B"	-35,400 = -2A
$\beta$ -Chondrosamine pentacetate....	+101.3°	+39,500 = +A + B"	
$\alpha$ -Glucose pentacetate.....	+101.6°	+39,600 = +A + B'	38,100 = 2A
$\beta$ -Glucose pentacetate.....	+ 3.8°	+ 1,500 = -A + B'	

The values of 2A for the acetylated amino sugars agree closely with each other, the disagreement corresponding to only about 1.5° in specific rotation. With the glucose pentacetates the agreement is not so good, the divergence amounting to about 6° in specific rotation in one case and 7.5° in the other. These facts seem to indicate that the nature of the groups on the chain have in this case a definite, though small, influence upon the rotation of the end asymmetrical carbon atom.

### Experimental.

**Preparation of Glucosamine Hydrochloride and the  $\alpha$ - and  $\beta$ -Glucosamine Pentacetates.**—Glucosamine hydrochloride was prepared both from lobster shells and crab shells. Both materials gave a good yield of the amino sugar, but crab shells had the advantage in being cleaner and easier to work with. The lobster shells required a preliminary treatment with caustic soda whereas the crab shells were immediately digested with 5% HCl. This treatment was continued with one or two renewals of the acid until the evolution of CO<sub>2</sub> had ceased. The softened shells were washed and boiled with concentrated HCl, more acid being added from time to time until the shells were completely decomposed and the whole mass had become a thick, black mush. This was diluted with three times its volume of water, warmed with the addition of some active decolorizing carbon such as "eponite" or "norit" and filtered. The filtrate, which was clear and colorless, on evaporation under diminished pressure, crystallized in the flask. The crystals were filtered off and washed with 75% alcohol. The product thus prepared was nearly pure hydrochloride of glucosamine.

The acetylation of this compound was carried out with sodium acetate and acetic anhydride according to the directions of Lobry de Bruyn and Van Ekenstein.<sup>2</sup> The less soluble isomer, the  $\beta$ -pentacetate, was recrystallized from alcohol until its specific rotation became constant. The pure substance melted at 118–189° corr. With chloroform as solvent 1.0828 g. of this compound per 25 cc. of the solution gave a reading to the right +0.1° in a two decimeter tube with sodium light, hence

<sup>1</sup> All specific rotation measurements were made in chloroform (*chloroformum purificatum*, U. S. P.) solution.

<sup>2</sup> *Loc. cit.*

$[\alpha]_{20}^D = +1.2^\circ$ . After another recrystallization a duplicate measurement in which 1.1092 g. of the compound were used gave  $[\alpha]_{20}^D = +1.3^\circ$ .

An acetyl determination made by boiling 0.3034 g. of the acetate with 20%  $\text{H}_2\text{SO}_4$ , distilling off the acetic acid into a flask and titrating with 0.1 N NaOH gave 77.13% acetic acid, which agrees with the theoretical value 77.12% for pentacetyl glucosamine.

The more soluble isomer, the alpha pentacetate, was recrystallized from water, then from alcohol and then from ether until its specific rotation became constant. The pure compound melted at  $139\text{--}140^\circ$  corr. With chloroform as solvent, 1.2762 g. gave a reading to the right  $+9.55^\circ$  in a two decimeter tube with sodium light, hence  $[\alpha]_{20}^D = +93.5^\circ$ . A duplicate measurement using 1.0561 g. of the substance gave  $[\alpha]_{23}^D = +93.3^\circ$ .

An acetyl determination gave 77.25% acetic acid.

**Preparation of  $\alpha$ -Chondrosamine Pentacetate.**—The first supply of chondrosamine hydrochloride was obtained through the courtesy of Dr. P. A. Levene, of the Rockefeller Institute for Medical Research. A later supply was prepared by Mr. E. P. Clark, of this laboratory, according to the directions of Levene and LaForge.<sup>1</sup>

The acetylation of this amino sugar was easily accomplished. To 80 cc. of acetic anhydride in which had been dissolved twelve grams of zinc chloride were added 10 g. of chondrosamine hydrochloride, which went rapidly into solution with the development of considerable heat. The reaction mixture was poured into about 200 cc. of water and the acid nearly neutralized with sodium bicarbonate. From this solution crystals of a compound separated out which proved to be a pentacetyl derivative of chondrosamine. It was recrystallized from alcohol until its specific rotation became constant. The yield of the pure substance was about equal to the weight of the hydrochloride used.

The pure compound did not melt, but commenced to turn brown at  $220^\circ$  and was completely decomposed at  $235^\circ$ . It was insoluble in cold water, alcohol and ether, and only slightly soluble in chloroform and acetone. In chloroform solution 0.2500 g. per 50 cc. of the solution gave a reading to the right  $+0.21^\circ$  in a four decimeter tube with sodium light, hence  $[\alpha]_{20}^D = +10.5^\circ$ . After another recrystallization a duplicate measurement gave  $[\alpha]_{20}^D = +11.0^\circ$ .

An acetyl determination made by boiling 0.3050 g. of the compound with 20%  $\text{H}_2\text{SO}_4$ , distilling off the acetic acid and titrating with 0.1 N NaOH gave 77.22% acetic acid. A duplicate gave 76.91% acetic acid. The theoretical amount for chondrosamine pentacetate is 77.12%.

0.2481 g. subst. gave 0.4502 g.  $\text{CO}_2$  and 0.1359 g.  $\text{H}_2\text{O}$ , corresponding to 49.48% C and 6.13% H; 1.000 g. of the substance gave 3.25% N by the Kjeldahl method.

Calc. for  $\text{C}_{18}\text{H}_{28}\text{O}_{10}\text{N}$ : 49.33% C, 5.96% H, and 3.61% N.

<sup>1</sup> *J. Biol. Chem.*, 18, 126 (1914).

**Transformation of  $\alpha$ -Chondrosamine Pentacetate to the Isomeric Beta Form.**—When the  $\beta$ -chondrosamine pentacetate was dissolved in acetic anhydride containing a small amount of  $\text{ZnCl}_2$ , the rotation was found to change upwards from an initial specific rotation of about  $12^\circ$  to a final value of about  $65^\circ$ . After the rotation had reached a constant value the solution was poured into water and the acid nearly neutralized with sodium bicarbonate. A quantity of the original pentacetate separated out at this point. On extracting the mother liquor with chloroform and evaporating the chloroform extract, crystals of a substance were obtained which proved to be the isomeric alpha chondrosamine pentacetate. The following has proved to be a convenient method for the preparation of this compound. Twelve grams of  $\alpha$ -chondrosamine pentacetate were dissolved at the temperature of the steam bath in 100 cc. of acetic anhydride containing about two grams of  $\text{ZnCl}_2$ . The heating was continued until no further change in the rotation was noticed. The solution was poured into 300 cc. of water and the acid nearly neutralized with sodium bicarbonate. The solution was cooled in ice and the crystals of the original substance which here separated out were filtered off. The filtrate was extracted with chloroform and the chloroform extract evaporated to a small volume. On stirring in absolute ether, crystals of the new compound mixed with a small amount of the  $\alpha$ -form separated out. The  $\beta$ -pentacetate was freed from the  $\alpha$ -isomer by dissolving the mixture of crystals in a small amount of absolute alcohol and adding five times this volume of absolute ether. The  $\alpha$ -pentacetate immediately crystallized out and was filtered off. The  $\beta$ -pentacetate was crystallized by evaporating the filtrate in a current of air with the addition from time to time of small quantities of absolute ether. The substance was recrystallized by the above method until its specific rotation became constant and then once more by adding absolute ether to its solution in chloroform. The melting point of the pure substance was  $182\text{--}183^\circ$  corr. This compound is very soluble in cold water, alcohol, ethyl acetate and chloroform, which is in marked contrast to the extreme insolubility of the  $\alpha$ -isomer. In chloroform solution 0.8053 g. of the compound per 25 cc. of the solution gave a reading to the right,  $+6.58^\circ$  in a two decimeter tube with sodium light, hence  $[\alpha]_{17}^D = +102.1^\circ$ . A duplicate measurement in which 0.5343 g. of the substance was used gave  $[\alpha]_{18}^D = +101.3^\circ$ .

Two acetyl determinations made by boiling 0.3075 g. and 0.4169 g. of the  $\beta$ -pentacetate with 50 cc. of 20%  $\text{H}_2\text{SO}_4$ , distilling off the acetic acid and titrating it against 0.1 N NaOH gave 77.03% and 77.30% acetic acid, which agrees with the theoretical, 77.12%.

0.3390 g. gave 0.6122 g.  $\text{CO}_2$  and 0.1832 g.  $\text{H}_2\text{O}$ , corresponding to 49.25% C and 6.05% H; 1.000 g. gave 3.55% N by the Kjeldahl method.

Calc. for  $\text{C}_{16}\text{H}_{22}\text{O}_{10}\text{N}$ : 49.33% C; 5.96% H; 3.61% N.

WARRINGTON, D. C.

## NEW BOOKS.

**Chemistry in the High School.** By E. P. SCHOCH, Professor of Physical Chemistry in the University of Texas, Bulletin 329 and 375 University of Texas. Price, 50 cents.

The book is divided into three parts: I. Equipment; II. A Course of Lessons and Exercises in General Chemistry; III. 'Teachers' Manual. Part I consists of a general discussion of methods to equip the laboratory with respect both to efficiency and economy. In Part II we find a decided departure from the usual arrangement in texts on general chemistry. By omitting all descriptive chemistry the author has brought out in a very clear manner sequence in the development of the subject, leading from the simplest kind of chemical reaction gradually to the more difficult. In the treatment of each kind of reaction, exercises and experiments are given in considerable number illustrating that particular class to the exclusion of all others, as nearly as possible.

The subject is developed in general from the physical chemical standpoint. In the chapter on acids, bases and salts, much time is devoted to conductance experiments illustrating percentage of ionization and metathetical reactions with the idea of showing why the latter take place. In the treatment of oxidation-reduction reactions free use is made of the principles of the electric cell and several experiments are given to show the relation between chemical action in the cell and the general oxidation-reduction reaction. Practically no space, however, is devoted to the illustration of the fundamental laws.

The book gives many references to commercial applications, illustrating the processes used by well-selected experiments. A good descriptive text, as the author states, would have to be used in connection with it. In order to enable the teacher to better correlate the two, Part III is appended which gives many suggestions and ideas that will undoubtedly be of a good deal of help, especially to the inexperienced teacher.

GEO. W. SEARS.

**"Changes in the Food Supply and Their Relation to Nutrition."** By LAFAYETTE B. MENDEL. Yale University Press: New Haven, 1916. 61 pp. Price, 50 cents.

This essay, written for the Second Pan American Scientific Congress at Washington, December, 1915, discusses the production, conservation, preservation, transportation, canning, and refrigeration of food; the deficiency diseases, food requirements, one-sided dietaries, the chemistry of the proteins, the use of oils, customs in diet, and the effect of industrial and social changes as well as other economic and hygienic factors upon the nutrition of nations. These topics are woven together by the author into an exceedingly interesting and stimulating presentation of modern thought on the problems of nutrition and of food economics. The re-

sults of modern research in physiological science are brought to bear upon the problem of the world's food supply, and it is shown that it is idle to make such prophecies as that of Sir William Crookes that the world's wheat supply will soon prove inadequate for the maintenance of the world's inhabitants. It would be hard for both scientists and laymen to find a more illuminating presentation in so small a compass.

THE DISSOCIATION TENSIONS OF CERTAIN HYDRATED  
CHLORIDES AND THE VAPOR PRESSURES OF  
THEIR SATURATED SOLUTIONS.<sup>1</sup>

BY I. H. DERBY AND VICTOR YNGVE.

Received May 13, 1916.

A knowledge of the vapor-pressure relationships of certain hydrated chlorides was required in connection with a problem which is being studied in this laboratory. Since the required data could not be found in the literature, the measurements which follow were made to supply this deficiency. Partington<sup>2</sup> and Foote and Scholes<sup>3</sup> have classified and critically discussed the methods which have been employed for the measurement of the vapor pressures of hydrates. None of the methods they mention seem to combine accuracy, simplicity and ease of manipulation as well as the static method of Smith and Menzies.<sup>4</sup> Since this method is described at length in the exhaustive study cited, only essential details of the apparatus and the precautions taken to secure data of the desired degree of accuracy 0.1 to 2 mm. will be given.

<sup>1</sup> Presented at the meeting of the American Chemical Society, Urbana, Ill., April, 1916.

<sup>2</sup> Partington, *J. Chem. Soc.*, 99, I, 466 (—).

<sup>4</sup> Smith and Menzies, *THIS JOURNAL*, 32, 1412 (1910).

### The Apparatus.

The *isoteniscope* was of the ordinary static type. The confining liquid in all these measurements was a heavy paraffin oil.

Temperature regulation was obtained at the various temperatures below  $75^{\circ}$ , by immersing the *isoteniscope* in a 10 l. cylindrical glass thermostat heated by the method of Derby and Marden.<sup>1</sup>

The especially designed toluene-mercury regulator used allowed of convenient adjustment of temperature of the thermostat at any point within a range of about sixty degrees. At temperatures from above  $50^{\circ}$  up to  $75^{\circ}$  the water in the thermostat was covered with a layer of low melting paraffin. In all cases the regulation was constant within  $0.05^{\circ}$ . For the higher temperatures above  $75^{\circ}$  a benzene-toluene-xylene vapor bath was used. This bath when fitted with a reflux condenser remained constant within  $0.1^{\circ}$ .

The manometer was of the open-end type. The tube of 1 cm. inside diameter was mounted upon a support of thoroughly seasoned wood which bore a paper scale covered with Bakelite varnish. The scale was carefully calibrated by means of a standard cathetometer and during its use showed no variation due to atmospheric changes. After the manometer was permanently placed and adjusted to a truly vertical position, the length of the scale was determined *in situ* by means of a cathetometer. From these observations a scale correction curve was constructed. Scale readings were made by means of a cathetometer to avoid parallax and to give a scale magnification and were estimated to tenths of a millimeter. The barometer, which was read to the nearest tenth of a millimeter, was compared with a standard instrument and the readings were found to be correct. All manometer and barometer readings were corrected to  $0^{\circ}$ . The manometer mercury was purified by dropping it through dilute nitric acid and distilling *in vacuo*.

The *thermometer* used below  $100^{\circ}$  was compared with one recently standardized by the Bureau of Standards and had no scale correction. The thermometer used above  $100^{\circ}$  was corrected at  $100^{\circ}$  by taking the boiling point of water in the usual way. It was then compared with a thermometer certified to  $0.2^{\circ}$  by the Reichsanstalt. In all cases where it was appreciable a correction was made for exposed thread.

**Preliminary Measurements.**—In order to test the accuracy of the method and the applicability of paraffin oil as a confining liquid in the *isoteniscope*, trial measurements of the vapor pressures of water at four temperatures were made. In Table I, under *I*, are given the number of observations made at each temperature, under *t* are given the corrected temperatures, under *p*<sub>1</sub> are given the vapor pressures found, and under *p* are given the values of Scheel and Heuse at the same temperatures taken from the

<sup>1</sup> Derby and Marden, *THIS JOURNAL*, **35**, 1767 (1913).

tables of Landolt-Börnstein. The pressures are given in mm. of mercury.

TABLE I.—VAPOR PRESSURES OF WATER.

I.	<i>t</i> .	<i>p</i> <sub>1</sub> .	<i>p</i> .	Difference.
2.....	25.09	24.0	23.89	+0.1 mm.
2.....	34.15	40.3	40.25	+0.0 mm.
2.....	43.41	66.4	66.22	+0.2 mm.
3.....	54.64	115.8	116.08	—0.3 mm.

It will be seen that the observed values are in good agreement with the true values. Paraffin oil then could safely be employed at least to 55° and above this temperature the errors must be well within a millimeter even at 70–80°. Larger errors due to the vapor pressure of the oil above this temperature would not obscure the relative relationships although leaving the true values somewhat in doubt.

### The Vapor-pressure Relationships of Magnesium Chloride-Water.

The following  $\text{MgCl}_2\text{-H}_2\text{O}$  systems were studied: Saturated solution of  $\text{MgCl}_2\cdot 6\text{H}_2\text{O}$ , saturated solution of  $\text{MgCl}_2\cdot 4\text{H}_2\text{O}$ , and the system  $\text{MgCl}_2\cdot 6\text{H}_2\text{O-MgCl}_2\cdot 4\text{H}_2\text{O}$ . Pure magnesium chloride was recrystallized once from distilled water, washed and dried in a centrifuge fitted with a porcelain basket. Six determinations of the vapor pressure of the saturated solution of the uncrystallized salt at 23.16° gave a mean value of 6.9 mm., while the value at the same temperature for the vapor pressure of the saturated solution of the recrystallized salt was 6.8 mm. The difference is within the limit of error of the method.

In almost all cases where two systems were being studied over the same range of temperature two isoteniscopes were used simultaneously in parallel and so arranged that, by means of suitable stopcocks, either one or both could be connected with the manometer. In this way, as the transition temperature was approached, the method became a differential one and the transition temperature could be determined as exactly as by means of the more cumbersome Frowein tensimeter.

In all these measurements, as well as those which follow, care was taken to bubble vapor out of the bulb in order to secure complete removal of air and, in the case of solutions, to insure saturation. Since the isoteniscopes were connected to the manometer by means of thick-walled rubber tubing, the apparatus was flexible enough to allow the bulbs to be shaken. This, and the small amounts of material needed, insured saturation in the shortest possible time.

In the tabulations for the various systems studied the following abbreviations are used to designate the phases which enter into the equilibrium: Stl. = saturated solution. V. = vapor.  $6\text{H}_2\text{O}$ ,  $4\text{H}_2\text{O}$ , etc., designates the degree of hydration of the salt in the solid phase. For example,  $6\text{H}_2\text{O-Stl.-V.}$  signifies that the phases in equilibrium are for magnesium chloride and water,  $\text{MgCl}_2\cdot 6\text{H}_2\text{O-saturated solution-vapor.}$

Under the phases is placed the temperature range over which the relationship was studied. The curves are also designated by the phases in equilibrium.

In Table II, under *I*, are given the number of observations at each temperature, under *t* are given the temperatures, under *p* are given the vapor pressures of the saturated magnesium chloride solutions. Below 117.2° the solid phase is  $\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$ , while above that temperature the solid phase is  $\text{MgCl}_2 \cdot 4\text{H}_2\text{O}$ . Under *p*<sub>6</sub> are given the dissociation tensions of the system  $\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$ – $\text{MgCl}_2 \cdot 4\text{H}_2\text{O}$ .

The vapor-pressure curves of the  $\text{MgCl}_2 - \text{H}_2\text{O}$  systems studied are shown in Fig. 1. A T is the vapor-pressure curve of the saturated solutions of the hexahydrate. It will be noted that the curve becomes retroflex near the transition temperature T. This is due to the large increase in solubility of the hydrate near its transition temperature. T C is the vapor-

<sup>1</sup> Extrapolated.

pressure curve of the saturated solutions of the tetrahydrate. D T is the vapor-pressure curve of the system  $\text{MgCl}_2 \cdot 6\text{H}_2\text{O} - \text{MgCl}_2 \cdot 4\text{H}_2\text{O}$ . It intersects the curve A T at T.

Fig. 1.

### The Vapor-pressure Relationships of Cupric Chloride Water.

Saturated solutions of  $\text{CuCl}_2 \cdot 2\text{H}_2\text{O}$  and the system  $\text{CuCl}_2 \cdot 2\text{H}_2\text{O} - \text{CuCl}_2 \cdot \text{H}_2\text{O}$  were studied. The cupric chloride was made from the sulfate by precipitation with sodium carbonate and solution in hydrochloric acid. The twice crystallized salt still showed the presence of small amounts of sulfate. The results should not be affected by this impurity since the sulfate hydrate has a lower vapor pressure than the chloride hydrate.

In Table IV, under I, are given the number of observations at each temperature, under  $t$  are given the temperatures, under  $p$  are given the vapor

pressures of the saturated cupric chloride solutions and under  $p_2$  are given the dissociation tensions of the system  $\text{CuCl}_2 \cdot 2\text{H}_2\text{O} - \text{CuCl}_2 \cdot \text{H}_2\text{O}$ .

The vapor-pressure curves of the  $\text{CuCl}_2\text{-H}_2\text{O}$  systems studied are shown in Fig. 2. A B is the vapor-pressure curve of the solution in equilibrium with  $\text{CuCl}_2\cdot 2\text{H}_2\text{O}$ , while C D is the vapor-pressure curve of the system  $\text{CuCl}_2\cdot 2\text{H}_2\text{O-CuCl}_2\cdot \text{H}_2\text{O}$ .

### The Vapor-pressure Relationship of Cobalt Chloride Water.

The following  $\text{CoCl}_2\text{-H}_2\text{O}$  systems were studied: Saturated solutions of  $\text{CoCl}_2\cdot 6\text{H}_2\text{O}$ , saturated solutions of  $\text{CoCl}_2\cdot 2\text{H}_2\text{O}$ , and the system  $\text{CoCl}_2\cdot 6\text{H}_2\text{O-CoCl}_2\cdot 2\text{H}_2\text{O}$ . Pure cobalt chloride was recrystallized from distilled water, washed and dried in a centrifuge fitted with a porcelain basket. Careful testing with dimethyl glyoxime failed to reveal any trace of nickel.

In Table VI, under I, are given the number of observations at each temperature, under *t* are given the temperatures, under *p* are given the vapor pressures of the saturated cobalt chloride solutions. Below 52.25° the solid phase was the hexahydrate while above that it was the dihydrate. Under *p*<sub>6</sub> are given the dissociation tensions of the system  $\text{CoCl}_2\cdot 6\text{H}_2\text{O-CoCl}_2\cdot 2\text{H}_2\text{O}$ .

The vapor-pressure curves of the  $\text{CoCl}_2\text{--H}_2\text{O}$  systems studied are shown in Fig. 3. The curve A T is the vapor-pressure curve of the solutions in equilibrium with  $\text{CoCl}_2 \cdot 6\text{H}_2\text{O}$ . There is a slight tendency for the curve

Fig. 3.

<sup>1</sup> Extrapolated.

to flatten out as it approaches the transition point  $T$ . This is due to the increased solubility of the hydrate. The curve  $TC$  is the vapor-pressure curve of the solutions in equilibrium with  $\text{CoCl}_2 \cdot 2\text{H}_2\text{O}$ . The curve  $BT$  is the vapor-pressure curve of the system  $\text{CoCl}_2 \cdot 6\text{H}_2\text{O} - \text{CoCl}_2 \cdot 2\text{H}_2\text{O}$ . It intersects the curve  $AT$  at  $T$ .

Water vapor was removed from the saturated cobalt chloride solution at a temperature above the transition point until a fall in the vapor pressure indicated the presence of a new phase. At  $56.3^\circ$  the pressure was 4.9 mm., and at  $60.7^\circ$  the pressure was 5.6 mm. (see points  $a$  and  $b$ , Fig. 3). The chloride content of the bulb was then determined by titration with  $0.1\text{ }N$   $\text{AgNO}_3$  using  $\text{K}_2\text{CrO}_4$  as an indicator. The degree of hydration was then calculated and the salt was found to contain 1.82 molecules of water. No evidence of the existence of the tetrahydrate was found.

The vapor-pressure measurements were not refined enough to show any indication of the polymorphic change of the red hexahydrate into the blue hexahydrate which occurs below the transition temperature.

#### The Vapor-pressure Relationship of Nickel Chloride Water.

Vapor-pressure measurements were made on the following  $\text{NiCl}_2 - \text{H}_2\text{O}$  systems: Solutions in equilibrium with  $\text{NiCl}_2 \cdot 6\text{H}_2\text{O}$ ; solutions in equi-

librium with  $\text{NiCl}_2 \cdot 4\text{H}_2\text{O}$ ; the system  $\text{NiCl}_2 \cdot 6\text{H}_2\text{O}$ – $\text{NiCl}_2 \cdot 4\text{H}_2\text{O}$ ; and the system  $\text{NiCl}_2 \cdot 4\text{H}_2\text{O}$ – $\text{NiCl}_2 \cdot 2\text{H}_2\text{O}$ . The degree of hydration of the last two systems was determined in the manner referred to above for cobalt and they were found to contain 5.74 and 3.78 molecules of water, respectively. The nickel chloride used was "Highest Purity" and was not recrystallized.

In Table VIII, under  $I$ , are given the number of observations at each temperature, under  $t$  are given the temperatures, under  $p$  are given the vapor pressures of the solutions in equilibrium with  $\text{NiCl}_2 \cdot 6\text{H}_2\text{O}$ , under  $p'$  are given the vapor pressures of the solutions in equilibrium with  $\text{NiCl}_2 \cdot 4\text{H}_2\text{O}$ , under  $p_6$  are given the dissociation tensions of the system  $\text{NiCl}_2 \cdot 6\text{H}_2\text{O}$ – $\text{NiCl}_2 \cdot 4\text{H}_2\text{O}$ , and under  $p_4$  are given the dissociation tensions of the system  $\text{NiCl}_2 \cdot 4\text{H}_2\text{O}$ – $\text{NiCl}_2 \cdot 2\text{H}_2\text{O}$ .

The vapor-pressure values at every  $5^\circ$ , taken from the curve, are given in Table IX.

The vapor-pressure relationships of the  $\text{NiCl}_2$ – $\text{H}_2\text{O}$  systems studied are shown in Fig. 4. The curve A T D is the vapor-pressure curve of the solution in equilibrium with  $\text{NiCl}_2 \cdot 6\text{H}_2\text{O}$ . Here again there is a tendency for the curve to flatten out as it nears the transition point T. We have not noticed any reference in the literature to this increase in solubility of a hydrate near its transition temperature. It would seem to indicate that changes in the physical behavior of a hydrate precede its transformation into a lower hydrate. The curve extends into the unstable region above the transition temperature to D. Here the vapor pressure of the unstable system is lower than that of the stable system. Findley<sup>2</sup> has pointed out that this is due to the greater solubility of the unstable hydrate. The curve B T is the vapor-pressure curve of the system

Extrapolated.

<sup>2</sup> Findley, "The Phase Rule," p. 144.

$\text{NiCl}_2 \cdot 6\text{H}_2\text{O} - \text{NiCl}_2 \cdot 4\text{H}_2\text{O}$ . It cuts the curve A T D at T. The curve T C is the vapor-pressure curve of the solutions in equilibrium with  $\text{NiCl}_2 \cdot 4\text{H}_2\text{O}$ . It is practically a continuation of the curve B T. The curve

Fig. 4.

E F is the vapor-pressure curve of the system  $\text{NiCl}_2 \cdot 4\text{H}_2\text{O} - \text{NiCl}_2 \cdot 2\text{H}_2\text{O}$ . This should cut the curve T C approximately at  $75^\circ$ ,<sup>1</sup> the transition temperature of the tetrahydrate into the dihydrate. The curves when

<sup>1</sup> Etard, *Ann. chim. phys.*, [7] 2, 545 (1894).

extrapolated, as shown by the dotted lines, intersect at about this point. The transition of the hexahydrate into the tetrahydrate which takes place at  $36.25^\circ$  has never been noted before. Lescoeur<sup>1</sup> found no evidence of the tetrahydrate. The measurements given here seem to point clearly to its existence.

### Summary.

The static method of Smith and Menzies has been employed in determining the dissociation tensions of hydrates and the vapor pressures of their saturated solutions. The method has been found convenient and the data given by it have been consistent and of the required degree of accuracy.

The following systems were studied over the indicated temperature range and transition temperatures were observed as listed:

Systems.	Temp. range.	Transition temp
Components $\text{MgCl}_2\text{-H}_2\text{O}$ .		
$\text{MgCl}_2.6\text{H}_2\text{O-Stl.-V}$ .....	$10.14^\circ\text{-}117.2^\circ$	....
$\text{MgCl}_2.4\text{H}_2\text{O-Stl.-V}$ .....	$117.2^\circ\text{-}138.3^\circ$	....
$\text{MgCl}_2.6\text{H}_2\text{O-MgCl}_2.4\text{H}_2\text{O-V}$ .....	$31.6^\circ\text{-}115.6^\circ$	$117.2^\circ$
Components $\text{CuCl}_2\text{-H}_2\text{O}$ .		
$\text{CuCl}_2.2\text{H}_2\text{O-Stl.-V}$ .....	$26.60^\circ\text{-}64.45^\circ$	....
$\text{CuCl}_2.2\text{H}_2\text{O-CuCl}_2\text{H}_2\text{O-V}$ .....	$17.90^\circ\text{-}64.18^\circ$	....
Components $\text{CoCl}_2\text{-H}_2\text{O}$ .		
$\text{CoCl}_2.6\text{H}_2\text{O-Stl.-V}$ .....	$23.40^\circ\text{-}52.25^\circ$	....
$\text{CoCl}_2.2\text{H}_2\text{O-Stl.-V}$ .....	$52.25^\circ\text{-}78.87^\circ$	....
$\text{CoCl}_2.6\text{H}_2\text{O-CoCl}_2.2\text{H}_2\text{O-V}$ .....	$23.05^\circ\text{-}52.25^\circ$	$52.25^\circ$
Components $\text{NiCl}_2\text{-H}_2\text{O}$ .		
$\text{NiCl}_2.6\text{H}_2\text{O-Stl.-V}$ .....	$19.80^\circ\text{-}36.25^\circ$	....
$\text{NiCl}_2.4\text{H}_2\text{O-Stl.-V}$ .....	$36.25^\circ\text{-}54.10^\circ$	....
$\text{NiCl}_2.6\text{H}_2\text{O-NiCl}_2.4\text{H}_2\text{O-V}$ .....	$19.80^\circ\text{-}36.25^\circ$	$36.25^\circ$
$\text{NiCl}_2.4\text{H}_2\text{O-NiCl}_2.2\text{H}_2\text{O-V}$ .....	$25.95^\circ\text{-}79.06^\circ$	....

The existence of  $\text{NiCl}_2.4\text{H}_2\text{O}$  hitherto in question has been definitely shown.

The tendency of  $p, t$  curves of saturated solutions of hydrated salts to become parallel to the  $t$  axis or even retroflex in close proximity to transition points has been noted in the systems studied. This change must result from a large increase in solubility as this point is reached. This relationship has been treated in detail by Roozeboom<sup>2</sup> from the thermodynamic standpoint.

Summary.

## 1. Introduction.

There is scarcely anything more important for a chemist than a knowledge of solubilities, but unfortunately he finds it more difficult to predict how soluble a substance will be in a given solvent than it is to predict almost any other important property. Bodländer,<sup>1</sup> it is true, has made approximate calculations of the solubility in water of some difficultly soluble salts from the electrode potentials of their ions and the heat of formation of the solid salts. Although this is a remarkable step in advance, it is of a very limited applicability, and it suffers, in common with Berthelot's principle of maximal work from the fact that the free energy of a chemical reaction is not equal to the total energy change. Planck<sup>2</sup> has pointed out that the relation between the change in free and total energy in forming a solution, and hence solubilities, could be calculated if we knew, in addition to the heat of solution, the specific heats of solution and pure substances down to absolute zero, the treatment being analogous to the calculation of chemical equilibria by means of the Nernst Heat Theorem. At present our meagre knowledge of specific heats of liquids and solutions makes such a treatment impossible. Furthermore, to be of real use, the calculation of solubility must be made from the properties of the pure substances only, and not from a property of the solution, such as its specific heat, the experimental determination of which may be more difficult than that of solubility itself.

Dolezalek<sup>3</sup> has shown how, assuming Raoult's Law for the vapor pressure of solutions, it is possible to calculate the solubility of gases in liquids. The validity of his calculations will be discussed later.

Washburn and Read<sup>4</sup> have also shown how it is possible to calculate the solubility of solids in liquids in cases where the substances obey Raoult's Law in the liquid state. The significance of this method of calculation is very great, but its scope is limited by the relatively small number of the mixtures which obey Raoult's law throughout the entire

range of concentration. If the deviations from this law, occurring in most solutions, could be accurately predicted, it would be possible to make accurate calculations of solubilities in general. It has not been possible up to the present time to give an accurate quantitative treatment for these deviations, and the difficulties in the way, it may be added, are very great. It is possible, however, to make certain generalizations of a more qualitative nature, and with their aid very useful predictions of solubility may be made in an approximate way.

## 2. Raoult's Law.

(a) **Kinetic Basis.**—A great deal of the older physical chemistry has had for one of its chief foundation stones the law of van't Hoff for the osmotic pressure of dissolved substances. The fruitful use of this law in dealing with the properties of dilute solutions, and its analogy to the laws for perfect gases, have somewhat blinded chemists to its limitations. Nearly all text-books of physical chemistry still use it to derive the ordinary laws for molecular weight determination, electromotive force of concentration cells, etc., and some investigators still ascribe any variations from these formulas to chemical changes, solvation, etc., forgetting that a large part of the deviation may be due to the inaccuracy of the fundamental equation for osmotic pressure. It has been pointed out by G. N. Lewis<sup>1</sup> and others that Raoult's law is a far better fundamental expression, holding for the simplest solutions throughout the entire range of concentration, when the van't Hoff equation leads to absurd values of osmotic pressure. In spite of the apparent probability of the van't Hoff law due to the analogy between gas pressure and osmotic pressure, it should be noted that Raoult's law has a simpler kinetic basis.

Let us consider a binary liquid mixture composed of  $n_1$  molecules of the component  $X_1$  and of  $n_2$  molecules of the other component,  $X_2$ . Let us denote the vapor pressures of the pure liquids by  $P_1$  and  $P_2$ , respectively, and their partial vapor pressures over the solution by  $p_1$  and  $p_2$ , respectively. If the vapors obey the gas laws, and if the molecules of  $X_1$  and  $X_2$  are sufficiently alike so that they are under the same forces in the mixture as in the pure liquids<sup>2</sup> then it follows, as a mere matter of logic, that since only the fraction  $\frac{n_1}{n_1 + n_2}$  of the molecules of the liquid are of the species  $X_1$ , that the partial pressure of  $X_1$  in the vapor phase,  $p_1$ , is the same fraction of what it would be,  $P_1$ , if all the molecules were of the same species. Hence we write

<sup>1</sup> G. N. Lewis, *THIS JOURNAL*, 30, 668 (1908).

<sup>2</sup> Washburn has defined this limitation by saying that the solution must have "constant thermodynamic environment." *Trans. Amer. Electrochem. Soc.*, 22, 333 (1912).

$$p_1 = P_1 \frac{n_1}{n_1 + n_2}, \text{ and similarly, } p_2 = P_2 \frac{n_2}{n_1 + n_2}. \quad (1)$$

We will consider presently how we may determine whether the molecules of different species are "sufficiently alike" to justify this conclusion, and first indicate, briefly, how the law makes possible the calculation of solubilities of gases and solids in liquids. These calculations have been fully made by the writers referred to, but the repetition seems desirable as an introduction to what is to follow in this paper.

(b) **The Solubility of Gases in Liquids.**—This is expressed in general by the familiar law of Henry, stating that the partial pressure of a gas and its solubility or concentration in a liquid are proportional. Letting  $X_1$  refer to the gas and  $X_2$  to the solvent, we would express this in our notation by the equation

$$p_1 = k \frac{n_1}{n_1 + n_2}.$$

The meaning of the constant  $k$  is made clear by putting  $n_2 = 0$ , when  $k$  becomes equal to the vapor pressure of the pure gas,  $P_1$ . If, as may often be the case, the solution is at a temperature higher than the critical temperature of the gas, then  $P_1$  must be an extrapolated value, as shown at X in Fig. 1. The usual equations giving the actual relation between

Fig. 1.

vapor pressure and temperature up to the critical temperature must include the effect of the deviation of the vapor from the gas laws as the critical temperature is approached, while Raoult's law, expressed as in this paper, presupposes that the vapor obeys the gas laws. It therefore seems more logical to find  $P_1$  from an equation like the familiar Clausius-Clapeyron equation, than it is to use some one of the empirical equations giving the actual vapor pressures near the critical point. We may say all of this more briefly by stating that  $P_1$  should be considered as the *fugacity* rather than the vapor pressure of the liquid, extrapolated above the critical point.

It should be noted that for the same gas at a given temperature the solubility in all liquids should be the same, according to Raoult's law, when it is expressed in terms of mol-fraction,  $N$ . When, however, it is expressed as the amount of gas in a given weight of solvent, the solvent with the higher molecular weight will dissolve less of the gas *per unit*

*weight*, since there are fewer mols in unit weight of the solvent in this case. Similarly, of two solvents having the same molecular weight, the solubility expressed as amount *per unit volume* of solvent will be greater in the denser solvent, since a unit volume of this solvent would contain more mols.

(c) **The Mutual Solubility of Liquids.**—Whenever liquid mixtures conform to Raoult's law they must be completely miscible, for if there were two liquid phases in equilibrium the partial vapor pressure of each component from each phase would have to be the same, and hence, by Raoult's law, the mol-fractions would be identical, and also the phases.

(d) **Solubility of Solids.**—In considering solutions of solids in liquids we must remember again, letting  $X_1$  denote the species forming the solid phase, that  $P_1$  is the vapor pressure, or better fugacity, of  $X_1$  in the *liquid* form.<sup>1</sup> Since the liquid is the unstable form of  $X_1$  below its melting point, the vapor pressure, or fugacity, of the solid form, which we will call  $P_1'$ , is less than  $P_1$  (see Fig. 2). If, then, solid  $X_1$  is gradually added to liquid

Fig. 2.

Fig. 3.

$X_2$ , the partial vapor pressure  $p_1$  will increase in proportion to the mol-fraction  $\frac{n_1}{n_1 + n_2}$  (which we will abbreviate into  $N_1$ ) until it becomes equal to  $P_1'$  (at  $x$  in Fig. 3), when no further increase is possible and hence the solution is saturated with respect to the solid, and  $N_1 = P_1'/P_1$ . If, then,  $P_1'/P_1$  can be determined, we can determine the solubility for substances of the class here considered. The ratio  $P_1'/P_1$  is given by the familiar equation<sup>2</sup>

<sup>1</sup> This important limitation has been overlooked by Strachan, *THIS JOURNAL*, 38, 626 (1196). It allows many solutions to remain in the category of ideal solutions that would be needlessly removed from this class by letting  $P_1$  depend on the appearance of a solid phase.

<sup>2</sup> This follows simply by taking the difference between the Clausius-Clapeyron equations for the solid and liquid phases.

$$\log \frac{P'}{P} = \frac{-L_0}{4.58T} + \frac{\Delta\Gamma}{1.99} \log T + I, \quad (2)$$

where  $L_0$  is the molal heat of fusion at absolute zero,  $\Delta\Gamma$  is the difference in the specific heats per mol of the liquid and solid forms, and  $I$  is an integration constant whose value is gotten by putting for  $T$  the melting point on the absolute scale, when  $\log \frac{P'}{P} = 0$ . When  $\Delta\Gamma$  is known  $L_0$  can be found from the molal heat of fusion at a temperature  $T$  by the relation

$$L = L_0 + \Delta\Gamma T. \quad (3)$$

When  $\Delta\Gamma$  is not known we can omit this term without much error, writing Equation 2 simply

$$\log \frac{P'}{P} = \frac{-L}{4.58T} + I. \quad (4)$$

It is obvious that the ratio  $\frac{P'}{P}$ , and hence the solubility of the solid, is smaller the greater the heat of fusion and the higher the melting point of the substance above the temperature chosen.

### 3. Deviations from Raoult's Law.

On investigating the actual vapor-pressure curves for mixtures of normal liquids we find rather good agreement with Raoult's law. Perfect agreement is illustrated graphically by Curve *a* in Fig. 3. With practically all solutions, unless dissociation occurs, the law is obeyed by each component when the other is present in but small amount. Graphically this means that the other types of curves for  $p$ , such as *b*, *c*, and *d*, in Fig. 3, become tangent to the straight line representing Raoult's law when  $N$  approaches unity. In most actual cases, however, as  $N$  becomes smaller, that is, as more of the other substance is added, the partial vapor pressure shows more or less deviation from Raoult's law. The actual pressure is greater than that given by Raoult's law in the majority of instances, as illustrated by *b*, Fig. 3, but is less than that calculated by Raoult's law in some cases, such as *c*, Fig. 3, especially when compounds between the two substances are suspected or known to exist. The percentage deviation generally becomes greater as  $N$  becomes smaller.<sup>1</sup>

These deviations exert a corresponding effect on the solubilities of gaseous or solid substances. Suppose, for example, the behavior is expressed by Curve *b*, Fig. 3, instead of by Curve *a*. This we will call a positive deviation from Raoult's law. It is obvious that saturation with solid  $X_1$  of vapor pressure  $P_1'$  will take place at a smaller value of  $N_1$  (point  $\gamma$ ) than it would be if the Curve *a* were followed (when the solution would

<sup>1</sup> For an exposition of these deviations see Roozeboom, "Heterogene Gleichgewichte" vol. 2 (1904).

be saturated at  $x$ ). Similarly, when a negative deviation from Raoult's law occurs, as shown by Curve  $c$ , more of  $X_1$  can be present in the solution before its partial pressure equals that of the pure solid,  $P_1'$  (at  $z$ ). The same considerations hold when  $X_1$  is a gas, when the partial pressure of the gas,  $p_1$ , takes the place of that of the solid,  $P_1'$ , in the foregoing discussion.

Two kinds of explanation have been offered to account for these deviations from Raoult's law. Dolezalek<sup>1</sup> assumes that any deviation from Raoult's law is caused by some effect which we may call chemical, a change in the number of mols due to the formation of a chemical compound between the two substances or else to a change in the degree of association of one or both constituents. Raoult's law is supposed to hold for each of the species of molecule present in the mixture. The results of this treatment are often quite plausible, and the writer himself has used it in explaining both the vapor pressure and e. m. f. of certain liquid amalgams.<sup>2</sup>

The other basis of explanation is that offered by the van der Waals theory, and has been discussed by van der Waals,<sup>3</sup> van Laar,<sup>4</sup> and Kohnstamm.<sup>5</sup>

Van Laar, for example, points out that we should expect deviations from Raoult's law, even when both liquids are normal, provided their critical pressures are different. He gives a formula involving the heat of mixing, and van der Waals' " $b$ ," and discusses the various types of vapor-pressure curve gotten by altering the constants in the formula.

Kohnstamm also applies the van der Waals theory in a general discussion of curve types.

It seems quite evident that calculations after the method of Dolezalek may be very often without significance. There are many mixtures of liquids, normal according to all ordinary criteria, which give vapor pressures greater than demanded by Raoult's law, one component of which would, according to Dolezalek, have to be considered as associated. Such, for example, are the following pairs: benzene and stannic chloride, bromine and carbon tetrachloride, carbon disulfide and methylal, benzene and hexane, benzene and ether, hexane and aniline. The degree of association that would have to be assumed to account for the observed deviations would entirely remove them from the class of normal liquids. In the case of hexane and aniline,<sup>6</sup> for example, two liquid phases are formed

<sup>6</sup> Unpublished work by Mr. D. B. Keyes of this laboratory.

below  $59.3^\circ$ , which denotes a partial vapor-pressure curve of the type denoted by  $d$  in Fig. 3. It is hard to imagine any kind or degree of association that would give this type of curve and still allow Raoult's law to hold for the various molecular species present. Certain it is that the assumption of the existence of double or triple molecular complexes even to a very great extent never leads to a deviation from Raoult's law sufficient to account for the formation of two liquid phases, as with this particular mixture.

Moreover, it is hard to be consistent in the use of this method when dealing with the same component in different mixtures. Thus, for example, acetone is undoubtedly an associated liquid, and account of this would have to be taken in explaining the vapor pressures when it is mixed with carbon disulfide. However, when dealing with the system acetone-chloroform, Dolezalek neglects such association while calculating the equilibrium involving the compound formed between the two substances.

On the other hand, the van der Waals theory, as applied by van Laar, is inadequate when one of the liquids is associated. Thus methyl alcohol and carbon disulfide, though having nearly equal critical pressures, deviate from Raoult's law to the extent of forming two liquid phases. It should be noted, in fairness, that van Laar recognizes the possibility of uncertainties of this nature.

(a) **Internal Pressure.**—If we seek a clue of a kinetic nature to the deviations from Raoult's law, we find it in the limitation stated earlier while giving the kinetic justification for the law, namely, that the molecules of  $X_1$  and  $X_2$  must be "sufficiently alike so that they are under the same forces in the mixture as in the pure liquids." It has seemed to the writer that the most satisfactory conception to serve as a basis for deciding whether the molecular forces are alike or not would be found in internal pressure. This is the force which, together with the external pressure, opposes the thermal pressure which is due to the kinetic energy of the molecules. In terms of the van der Waals equation

$$p = \frac{a}{v^2} - \frac{RT}{v - b}$$

it is the term  $a/v^2$ , the term  $RT/(v - b)$  being the thermal pressure. It is the cause of the tendency for the number of molecules in the surface of a liquid to be as small as possible, resulting in the phenomena of surface tension. Unfortunately, however, although the conception of internal pressure is a very fundamental one, its definition in experimental terms is very difficult and unsatisfactory. Several methods for calculating internal pressures have been proposed, and values have been published by a number of men. These values vary widely from one another

in the case of the same liquid, as will be seen in Table I. It is not our present purpose to undertake a critique of these calculations, as we are primarily interested in the relative rather than in the absolute values, and the order was found to be substantially the same by the different methods, except for the highly polar liquids, to be discussed later, where two effects are superimposed.

Table I contains values of the internal pressure in atmospheres accord-

ing to Winther,<sup>1</sup> Traube,<sup>2</sup> Walden,<sup>3</sup> W. C. McC. Lewis,<sup>4</sup> and Mathews.<sup>5</sup> The values by Winther, Traube and Lewis are for  $0^\circ$  as calculated by them. Walden gives values only at the boiling point, and in order to obtain values at the same temperature, so that they would be more suitable for comparison, the original values of Walden were reduced to  $0^\circ$  by assuming, according to the van der Waals' theory, that the variation in internal pressure is inversely proportional to  $v^2$ . Considering the uncertainty of the whole calculation, this part of it is relatively unobjectionable. Mathews gives in his paper values for the van der Waals " $a$ ." These were calculated to internal pressures at  $0^\circ$  by dividing by the square of the molecular volumes at that temperature. In the same table are given values for the critical pressures, selected from those given in Landolt-Börnstein. It is not surprising that the order for critical pressures, should be substantially the same, in most cases, as that for internal pressure, since in terms of the van der Waals theory critical pressure is given by  $\frac{8a}{27b^2}$ , while internal pressure is  $\frac{a}{v^2}$ , and  $b$  and  $v$  are closely related. It is well known, however, that the van der Waals equation, using the  $a$  and  $b$  calculated from critical data, does not satisfactorily represent the behavior even of non-associated liquids at much lower temperatures, nor is it possible to do so with any pair of fixed values of  $a$  and  $b$ . Moreover, it seems likely that, for normal liquids,  $b$  varies far more than  $a$ .<sup>6</sup> All of this renders it improbable that equality of critical pressures is the best criterion for our purpose, although it may be exceedingly convenient and useful. We might expect it to be of less value when the  $b$ -values (or molecular volumes) of the substances being compared are very different, and accordingly, as we shall frequently see, chlorine, whose  $b$ -value is small and which would take a considerably different position in the series if the latter were arranged according to critical pressures, behaves rather as we should expect it to when the series is arranged according to internal pressures.

We shall endeavor presently to show, according to the evidence at hand, that approximate equality of internal pressures of normal liquids is an adequate criterion for sufficient likeness in molecular environment for Raoult's law to hold. We shall also see that inequality of internal pressure indicates that the partial vapor pressures will be found greater than given by Raoult's law. It might be expected that two species of

molecules of different size and attractive power would pack less closely in the mixture than in the pure state, and that the volume of the mixture would be greater than additive, resulting in smaller attractions and greater vapor pressures. In fact, some preliminary calculations give some promise of a formal relation between this expansion, the assumed resulting decrease in internal pressure, and the increase in vapor pressure.

It may be mentioned that Walden, in the paper above referred to, gives a number of generalizations concerning the relation of internal pressure to constitution, in the case of organic liquids.

(b) **Polar Nature.**—There is another factor besides internal pressure which is of profound importance for which the van der Waals theory has not been able adequately to account, which has doubtless been the chief disturbing factor in its application to the liquid state, and in fact to a great deal of the work involving the mass law. That is the polarity of the substance. The nature of this polarity has been discussed by Bray and Branch,<sup>1</sup> and more fully by G. N. Lewis.<sup>2</sup> Molecules which are electrically polar will tend to form larger aggregates, or to associate, just as a mass of similar magnets would do. This polarity results in a molecular attraction, and hence an internal pressure and surface tension, which is greater than it would otherwise be. In an electric field such molecules tend to orient themselves according to their polarity, so that the liquid has a considerable dielectric constant. They also tend to form complexes with polar molecules of different species, "addition compounds." There is also a marked tendency for nonpolar or slightly polar substances to become more polar in the presence of polar substances, as shown, for example, by their greater reactivity when dissolved in polar solvents.

In liquids of this sort we should expect not only the *b* but also the *a* of van der Waals to be very abnormal and variable, and we can see more justification, in mixtures involving a polar liquid, for applying the method of Dolezalek, though even here we dare not assume that each molecular species present will obey the mass law and Raoult's law. The insuperable objection to this treatment seems to be raised by the liquids incompletely miscible, where we would have to make the paradoxical assumption previously mentioned that the mol-fractions are the same in two liquid phases of different composition.

If *X* and *Y* denote nonpolar and polar molecules, respectively, we should expect the attraction between *X* and *Y* to be greater than that between *X* and *X*, but less than that between *Y* and *Y*. This would cause a tendency for the *Y* molecules to form aggregates, even to the extent of separating as a separate phase of greater or less purity, and the deviations

<sup>1</sup> Bray and Branch, *THIS JOURNAL*, **35**, 1440 (1913).

<sup>2</sup> G. N. Lewis, *Ibid.*, **38**, 762 (1916).

from Raoult's law would be very great. In fact highly polar liquids nearly always form two-phase liquid systems with nonpolar liquids.

When two polar liquids are mixed we have rather complicated possibilities. If the attractions between  $Y_1$  and  $Y_2$  happened to be the same as those between  $Y_1$  and  $Y_1$  and between  $Y_2$  and  $Y_2$  we might find Raoult's law followed, but in general one species is more electropositive than the other, and the forces between  $Y_1$  and  $Y_2$  are the greatest, resulting in smaller vapor pressures than would otherwise be the case.

The polarity of a liquid is indicated experimentally by a high dielectric constant, an abnormally great entropy of vaporization,<sup>1</sup> deviation from the Eötvös-Ramsay and Shields rule for surface tension, power to give conducting solutions with electrolytic solutes, etc., etc.<sup>2</sup> A concordant figure for the degree of polarity or the "association factor" can hardly be obtained from the various methods, but we can indicate the polarity roughly by means of the dielectric constant. Values of the dielectric constant are, therefore, given in Table I, selected from those given in Landolt-Börnstein. Where other evidence would modify the conclusions based on the value of the dielectric constant a plus or minus sign is added to the figure to indicate the direction of the modification. For example, stannic chloride is a normal liquid, according to the usual criteria, and gives mixtures with benzene not deviating much from Raoult's law. On the other hand, it is evidently capable of becoming polar, as shown by its solubility and dissociation in water, and its chemical reactivity. It may well be that the symmetry of the molecule gives it, for example, slight moment in an electric field, and hence a small dielectric constant, although the charges within the molecule may be separated considerably, so that the proximity of a strongly polar molecule may distort it, rendering it polar. In the recent paper of G. N. Lewis entitled "The Atom and the Molecule" already cited, it is pointed out that the polar character of a substance is affected by its environment, a slightly polar substance, for example, becoming more polar in the presence of a strongly polar substance. There is no reason to believe that the curve he uses to point out the relation between polarity and "polar influence" would be the same for all substances. We may readily imagine that though two liquids may be equally nonpolar in the pure state they might be influenced unequally by the admixture of a highly polar substance. Such substances as stannic chloride, arsenic chloride, phosphorus trichloride, etc., seem to behave as fairly normal liquids in the pure state, and yet to be capable of polarity in the presence of highly polar substances. The distortion of a symmetrical molecule, previously mentioned, may serve to explain such cases.

If fused salts were included in Table I they would mostly come after

<sup>1</sup> Hildebrand, *THIS JOURNAL*, 37, 970 (1915).

<sup>2</sup> See W. E. S. Turner, "Molecular Association," Longmans, Green & Co., 1915.

water. All the evidence we have goes to show that many molten salts are far more polar than are even the dissociating solvents such as water and ammonia. The latter are not much ionized in the pure state, and their polarity must be due to a separation of the charges in the molecule. Fused salts, on the other hand, seem to be very highly ionized in the pure state, the separation of the charged parts being more or less complete into charged ions, as shown by the high conductivity of fused salts. The resulting liquids are highly abnormal, from the standpoint of the usual criteria, so far as they can be applied, although the term associated is hardly adequate to express their condition. The term polar is far more pertinent. The abnormal character and high internal pressure consequent upon this polar condition is evidenced chiefly by the high surface tension and the deviation from the Eötvös-Ramsay and Shields relation, such as are seen in the following values,<sup>1</sup> figures for water being included for comparison:

TABLE II.

	Temp.	Surface tension.	R. and S. constant.	"Assoc. factor."

H <sub>2</sub> O.....	20	73	1.13	3.56

Although our knowledge of fused salts is very meagre, we may doubtless make approximate predictions of their relative polarity to serve the purpose to be described later. We may assume that the polarity of a liquid salt is conditioned primarily by the electropositive and electronegative character of its constituents. This is indicated by the electrode potentials, and the electrochemical replacement series, where elements are concerned. This electrochemical character usually accords with the position of the element in the periodic table, the elements becoming increasingly electropositive as we go towards the alkali group, and also as we go from top to bottom of the principal groups. (In the subgroups, such as that including zinc, cadmium and mercury, the most electropositive elements may be found at the top.) The reverse is true for the electronegative character. Information is also gained from the relative strengths of acids and bases, the strongest being those showing the greatest tendency to ionize, and hence being most polar. In accordance with this the alkali halides, for example, would be highly polar, those of silver much less so, silver iodide being less polar than silver chloride. A

substance like lead chloride would be moderately polar, while lead acetate would be but slightly polar. The silicates of the heavier metals would be but slightly polar. An increase of polarity would result from increasing the electronegative character of a weak anion by the formation of a poly-anion, for example, a dichromate would be more polar than a chromate.

It seems, further, that atomic volumes have a great deal to do with polarity. Where these are great there would doubtless be more opportunity for the separation of the charges which produce polarity, the molecule being less compact, and we find, as a matter of fact, that the alkali metals, having the highest atomic volumes of all the elements, give highly polar compounds, followed in this respect by the halogens and the alkaline earths. The element having the smallest atomic volume of all, carbon, gives the least polar of all compounds. The "most normal" liquids we possess are the hydrocarbons of the paraffin series. The difference in atomic volumes may be responsible for the greater polarity of elementary iodine than of chlorine, as shown by the fact that its electrical conductivity in the liquid state is greater than that of chlorine,<sup>1</sup> and also by its greater reactivity. This polarity cannot be due to any difference in the two atoms composing the molecule, but rather to the electron being held under less constraint in the molecule, due possibly to the greater atomic volume as compared with chlorine.

The larger number of factors to be considered with polar liquids, and the lack of information as to their fundamental nature, cause our generalizations in the case of solutions of polar substances in each other to be much less accurate, but even here our predictions may have considerable value.

It will be remarked that in many respects the foregoing considerations concerning salts are essentially the same as those put forward by Abegg and Bodländer<sup>2</sup> in their theory of electro-affinity, which they also apply to the question of solubility. However, there are many serious contradictions that may be drawn from their considerations alone, which may be minimized by considering other factors simultaneously, especially the melting point and the heat of fusion. It must constantly be borne in mind that we are basing our discussion of the deviation from Raoult's law of a mixture of two liquids, and that where the solubility of solids is under discussion we must take into account, first, the polarity, internal pressure, etc., of the supercooled liquid, so far as we know them or are able to predict them, and, second, the instability of the supercooled liquid with respect to the solid form under discussion, as expressed by the ratio

<sup>1</sup> Linde, *Wied. An.*, **56**, 563 (1895); Lewis and Wheeler, *Z. physik. Chem.*, **56**, 179 (1906).

<sup>2</sup> *Z. anorg. Chem.*, **20**, 453 (1899).

P'/P, which may be calculated by the aid of Equation 2 or 4. A discussion of examples later will make this plainer.

The molten metals follow the fused salts at the bottom of the table, being represented by mercury. Here we probably have extreme polarity, the metal being highly dissociated into ions and electrons. However, it may still behave as a normal liquid according to some of the criteria. Mercury, for example, though abnormal according to the surface tension relationship,<sup>1</sup> is quite normal from the standpoint of the entropy of vaporization.<sup>2</sup> Certain it is that the internal pressures of the metals are so high as to preclude mixing with the other liquids, except in the case of the alkali metals in liquid ammonia, and in some fused salts.

We have little basis, as yet, for arranging the metals in the order of their internal pressures, but are left to infer the relative magnitudes of internal pressures from the surface tension, compressibility, and from the tenacity of the metal in the solid form. Table III gives a few values of surface tension selected from Landolt-Börnstein; also values of the compressibility, at 20° C., according to T. W. Richards.<sup>3</sup> One may infer that the internal pressures at the same temperature may increase in the order given in the table.

TABLE III.

	K.	Hg.	Pb.	Ag.	Fe.	Pt.
Temperature.....	62°	15°	325°	1000	1500	2000
Surface tension.....	412	436	510	782	1000	1800
Compressibility $\times 10^6$ at 20° .....	31.7	3.95	2.33	1.01	0.60	0.38

Thus, in spite of the high temperature at which it was observed, it will be noted that the surface tension of molten iron is very high compared with that of the softer metals. This, with the small compressibility and high tensile strength of solid iron, undoubtedly indicates a high internal pressure.

To summarize the effect of internal pressure and polarity, we may say that (1) Raoult's law should be obeyed by mixtures of nonpolar liquids having the same internal pressures; (2) nonpolar liquids of different internal pressures will show greater vapor pressures in the mixture than would be expected from Raoult's law; (3) the same holds true for mixtures of polar with nonpolar liquids; (4) mixtures of polar liquids may show either positive or negative deviations from Raoult's law, but in most cases the latter will predominate; (5) these deviations will modify the predictions of solubility for gases, liquids, and solids, based upon Raoult's law alone, the solubilities being greater where negative deviations occur, and *vice versa*.

#### 4. Experimental Evidence.

(a) **Liquid Mixtures.**—Having laid down our general principles, let us now compare their application with the observed facts. The following pairs of liquids give mixtures which obey Raoult's law exactly or nearly so: benzene and carbon tetrachloride,<sup>1</sup> benzene and chlorobenzene,<sup>2</sup> benzene and chloroform,<sup>2</sup> benzene and ethylene chloride,<sup>1</sup> chlorobenzene and toluene.<sup>2</sup> It will be observed that all of these liquids have nearly the same values of internal pressure. A small positive deviation, as we would expect, is found in the cases of ethyl iodide with ethyl acetate<sup>3</sup> and benzene with stannic chloride.<sup>4</sup> Larger deviations occur with benzene and carbon disulfide,<sup>5,6</sup> carbon disulfide and carbon tetrachloride,<sup>7</sup> benzene and hexane,<sup>8</sup> benzene and ether<sup>9</sup> and carbon disulfide and methylal.<sup>10</sup> Methylal is not given in the table but it is nonpolar, with a dielectric constant of only 2.7, and it must have a very low internal pressure, as Walden gives for acetal an internal pressure of 1000 atmospheres at 103°. The partial pressure of bromine in dilute solution in carbon tetrachloride is over twice the value calculated from Raoult's law.<sup>11</sup>

Chlorine, on the other hand, obeys Raoult's law rather closely in carbon tetrachloride solution. From the measurements of Jakowkin<sup>12</sup> on the solubility of chlorine in carbon tetrachloride we have calculated the following values for the mol-fraction of chlorine,  $N$ , and the ratio of the partial vapor pressure of chlorine to that of liquid chlorine at the same temperature,  $p/P$ .

$N$ .....	0.00086	0.00225	0.00423	0.00718
$p/P$ .....	0.00092	0.00268	0.00410	0.00673

The corresponding values are obviously almost within the limit of experimental error. This case is significant as showing that the internal pressures furnish a more reliable criterion than do critical pressures. In this case, as may be seen from the table, the former are much more nearly alike than the latter. If our table were arranged according to critical pressures chlorine would have a very different place.

(b) **Solubility of Gases.**—As explained previously, the ratio  $p/P$  for

a solution of a gas in a liquid gives its solubility where Raoult's law holds, even though the value of  $P$  for the gas has to be extrapolated above its critical pressure. The deviations from Raoult's law cannot be predicted with as much satisfaction as in the case of most of the solutions heretofore considered, because we have no knowledge of what places the gases should occupy in the table except as critical pressures may be used for the purpose. However, with the same gas, the solubility in various solvents should depend on the order of the internal pressures of the latter, subject, as always, to the further influence of polarity. The extent to which this is true is seen in Table IV. In calculating the figures here given use is made of the measurements of Just<sup>1</sup> on the solubilities of hydrogen, nitrogen, carbon monoxide and carbon dioxide. The values for methane, ethane, and ethylene are calculated from solubility measurements by MacDaniel,<sup>2</sup> and for ammonia in methyl and ethyl alcohol by de Bruyn.<sup>3</sup>

TABLE IV.<sup>4</sup>

Solubilities of Gases in Terms of Mol-Fraction,  $N \times 10^4$ , when  $p = 1$  Atmosphere.  
20° C.

$p/P$ for gas Solvent.	20° C.				25° C.			
	H <sub>2</sub> .	N <sub>2</sub> .	CO.	CO <sub>2</sub> .	CH <sub>4</sub> .	C <sub>2</sub> H <sub>6</sub> .	C <sub>2</sub> H <sub>4</sub> .	NH <sub>3</sub> .
	10	11	11	178	32	240	148	1020
Hexane.....	...	...	...	...	31	171	159	....
Xylene.....	4.0	6.1	8.9	...	26	...	...	....
Ethylacetate.....	3.2	6.8	9.9	...	..	123	...	....
Toluene.....	3.7	5.3	7.7	108	21	...	...	....

Carbon disulfide.....	...	1.3	2.0	23	..	...	...	....
Water.....	0.15	0.13	0.19	...	2.4	3.2	8.4	3300

The values of  $p/P$  were gotten by using the data found in Landolt-Börnstein, extrapolating above the critical pressure, where necessary, by the aid of the straight line plot obtained on plotting  $\log p$  against  $1/T$ .  $P$  is the pressure the liquefied gas would have at 20° and 25°, respectively;  $p$  is taken as 1 atmosphere. The solubilities, in terms of mol-fraction, are calculated also for a gas pressure of one atmosphere.

It will be seen that for nitrogen, carbon monoxide, methane, ethane and ethylene, the solubility in the various solvents decreases in essentially

<sup>3</sup> de Bruyn, *Rec. trav. chim.*, **11**, 112 (1892).

<sup>4</sup> The writer wishes to express his thanks to Mr. D. B. Keyes for help in the calculations required to prepare this table.

the order given in the table of internal pressures, the gas behaving, in this respect, as would a liquid of low internal pressure. The order for the different gases is not quite identical, but the slight discrepancies are hardly greater than the errors involved. As before, the greatest uncertainty is where the polar solvents are concerned. This is not surprising, as the uncertainties are necessarily greater in such cases on account of our inability to determine how much of the internal pressure is due to the polarity. Carbon dioxide is obviously, from its chemical reactivity, much more polar than the gases previously mentioned, and additional uncertainties are thus introduced, though a distinct increase in solubility in the more polar solvents is evident.

When we come to ammonia, itself highly polar, we find a solubility in polar solvents greater than that indicated by Raoult's law alone.

(c) **Liquids not Completely Miscible.**—Mr. Keyes and the writer have sought a pair of normal liquids that would be incompletely miscible, and have found that aniline, far down in the table, will not mix completely at lower temperatures with the paraffins, standing at the head of the table, though it will mix with all of the normal liquids standing nearer to it. Aniline is slightly polar, which helps to account for this behavior, but it is impossible to account for the deviation from Raoult's law evident in this case by any ordinary assumption as to association according to the method of Dolezalek.

As is well known, the highly polar liquids given in the table do not mix completely with the nonpolar liquids. The internal pressures and the polarity together make relative predictions quite trustworthy. Thus methyl alcohol, more polar than ethyl alcohol, does not mix completely with carbon disulfide whereas ethyl alcohol does. Water, still more polar, is scarcely soluble at all in carbon disulfide. Phenol is more polar than aniline and is accordingly much more soluble in water. Ethyl acetate, though having the same internal pressure as toluene, is much more polar, and hence is far more soluble in water. Other familiar facts are in general accord with the figures in the table.

(d) **Solubility of Solids.**—Iodine, calculated as a supercooled liquid, has the highest internal pressure of any of the normal substances in the table, and accordingly its solutions in most of the liquids represented show large deviations from Raoult's law. To make this evident we must calculate the ratio of vapor pressures for solid and liquid iodine for temperatures in the region of existing solubility measurements. Lewis and Randall<sup>1</sup> give the free energy of liquid iodine at 25° as 460 cal. per gram atom, corresponding to 920 cal. per mol. Since  $920 = -4.58 \times 298 \log P'/P$ , we have  $P'/P = 0.212$ . If Raoult's law held, this figure should represent also the solubility of iodine in terms of its mol-fraction at this tem-

<sup>1</sup> Lewis and Randall, *THIS JOURNAL*, 36, 2259 (1914).

perature. We have calculated the solubility in terms of mol-fraction in bromoform and carbon tetrachloride from measurements by Jakowkin.<sup>1</sup> The solubility in bromoform is given by him only in terms of amount of iodine per liter, so that we have had to make the assumption that the volume of the solution is additive, using for the volume of liquid iodine 59 cc. per mol.<sup>2</sup> The solubilities in carbon disulfide and benzene are gotten from measurements by Arctowski,<sup>3</sup> an extrapolation being necessary in the case of benzene to get the value at 25°. The solubility in chloroform is gotten from data by Hantzsch and Vagt,<sup>4</sup> an interpolation being necessary to reduce to 25°. The following are the resulting values:

	CHBr <sub>3</sub>	CS <sub>2</sub>	C <sub>6</sub> H <sub>6</sub>	CCl <sub>4</sub>	CHCl <sub>3</sub>
P'/P = 0.212; N = 0.066	0.066	0.058	0.047	0.026	0.022

Comparing the order of solubilities with that for internal pressures, we see that the solubility is greatest in bromoform, with the highest internal pressure, and the one nearest to iodine. The value in carbon disulfide comes next, as is to be expected. The internal pressures of the next three liquids are not far apart, and we might expect the solubilities in these liquids to be about the same. This is the case for chloroform and carbon tetrachloride. It is true the order here is reversed, but the moderate uncertainties of the figures for both the internal pressures and solubilities make the small discrepancy of scant significance. The only apparent exception of any magnitude is in the case of benzene, whose internal pressure is very close to those of carbon tetrachloride and chloroform but whose power of dissolving iodine appears to be nearly double what we might expect it to be. This is undoubtedly due to the fact that the solid phase is not pure iodine, but becomes a solid solution of benzene in iodine, as discovered by Beckmann and Stock,<sup>5</sup> allowing more iodine to enter the solution.

Solutions of naphthalene likewise show excellent agreement with the predictions made with the aid of the table. The mol-fraction of naphthalene in saturated solutions in several solvents is given in the following table, in comparison with the value P'/P, calculated from the measurements of Bogojawlenski<sup>6</sup> by means of Equation 2. The heat of fusion per mol is 4440 cal.,  $\Delta T = 5.1$ , the melting point is  $T = 353.1$ .

	CS <sub>2</sub>	CHCl <sub>3</sub>	C <sub>6</sub> H <sub>6</sub> CH <sub>3</sub>	C <sub>6</sub> H <sub>14</sub>	C <sub>2</sub> H <sub>5</sub> OH	P'/P	Temp.
N.....	0.253 <sup>8</sup>	0.303 <sup>7</sup>	.....	0.101 <sup>7</sup>	0.033 <sup>8</sup>	0.286	20°
	.....	.....	0.188 <sup>9</sup>	.....	.....	0.263	16.5°

<sup>1</sup> Jakowkin, *Z. physik. Chem.*, **18**, 585 (1895).

<sup>8</sup> Lobry, *Z. physik. Chem.*, **10**, 784 (1892).

<sup>9</sup> Bechi, *Ber.*, **12**, 1978 (1879).

As would be expected from the position of naphthalene in Table I, the values of  $P'/P$  are very close to the values of  $N$  in chloroform, a little less in carbon disulfide with its higher internal pressure, falling off, on the other hand, in toluene and hexane, with their successively lower internal pressures. The polar character of alcohol accounts for the very low solubility in that solvent.

Other data of similar nature is being obtained in this laboratory and will soon be ready for publication, all of which, thus far, is in entire accord with the predictions made.

(e) **Salt Solutions.**—We know so little about the properties of fused salts that we cannot predict relative solubilities in such cases with the certainty that is possible with less polar substances. Several generalizations, however, are possible.

The highly polar character of fused salts, previously referred to, causes all salts, so far as we have been able to determine, to be completely miscible in the liquid state.

The most highly polar salts would be the halides, nitrates, etc., of the alkali and alkaline earth metals, and accordingly these are generally very soluble in polar solvents, showing negative deviations from Raoult's law, in accordance with the principles earlier set forth. This is illustrated in Table V, where the solubility in water at  $25^\circ$  is given in terms

of mol-fraction, along with values of the melting point, and, where the heat of fusion is known,<sup>1</sup> values of  $P'/P$ , which would equal the solubilities if Raoult's law held. Calcium fluoride and barium sulfate we might

<sup>1</sup> Taken from the data given by Goodwin and Kalmus, *Phys. Rev.*, **28**, 1 (1909), see also Goodwin, *Trans. Am. Electrochem. Soc.*, **21**, 113 (1912) with the exception of the value for  $\text{KCl}$  by Plato, *Z. physik. Chem.*, **55**, 737 (1906), and that for  $\text{CaCl}_2 \cdot 6\text{H}_2\text{O}$ , by Person, *Ann. chim. phys.*, [3] **27**, 250 (1847).

expect to be highly polar in the liquid state. Their insolubility, in spite of polarity, is due to their high melting points, corresponding to a very small value of  $P'/P$ . If the heat of fusion were known, so that  $P'/P$  could be calculated, we would doubtless find that it is less than  $N$  in both cases, so that here, just as with potassium chloride and sodium nitrate, the deviation from Raoult's law would be negative, in accordance with the general principle. The negative deviation from Raoult's law has practically disappeared when we come to the salt of a much less electropositive metal like silver nitrate, and we find in general that the salts of the nobler and hence less electropositive metals become much less polar and less soluble in polar solvents, even if the melting point is not very high. Boric acid, in spite of its low melting point, has obviously very slight polarity, and is accordingly not very soluble in water. When we consider the sulfides of the heavier metals, and especially the silicates, we encounter both small polarity and high melting points, and consequently they are relatively insoluble. With the slightly polar compounds of lower melting point, however, like the acetates, mercuric iodide, etc., we find solubility in the weakly polar organic solvents, for here, as we should expect, the liquids do not show the strong positive divergence from Raoult's law that we find when a polar and a nonpolar substance are mixed.

It must be frankly stated that the mere guess as to the polarity of a molten salt is not sufficient to explain all of the facts. For example, silver iodide, which we might expect to be weakly polar, is far less soluble in water than it would be if Raoult's law held, but it is at the same time far more soluble in liquid ammonia, which is also very polar, although less so than water. We may make a generalization that cannot be deduced from the simple criteria of polarity that we have announced, though it, too, ought ultimately to be brought into accord with the physical properties of the substances, namely, that the tendency to form hydrates, and hence to give negative deviations from Raoult's law and greater solubility in water solution, is greatest for elements at the top of the Periodic Table, whereas the tendency to unite with ammonia, and hence, presumably, to be more soluble in liquid ammonia, is greatest for elements at the bottom of the table. This is illustrated by the abnormally high solubility of magnesium chloride in water, on the one hand, and by the abnormally high solubility of mercuric iodide and silver iodide in liquid ammonia, on the other hand.

In this connection it should be pointed out that the values of  $P'$  and  $P$  which determine the solubility are those of the actual phase which is in equilibrium with the solution. Thus it is the melting point and the heat of fusion of  $\text{CaCl}_2 \cdot 6\text{H}_2\text{O}$ , not of  $\text{CaCl}_2$ , which determine the solubility of calcium chloride at room temperatures. The same applies, of course,

to all solids with solvate of crystallization. Similar modifications must be made when the solid is a solid solution.

It may be stated, finally, that from our standpoint it probably makes little difference whether the solute and the solvent associate with each other to form a new polar complex, or whether there follows a separation of the parts of the original solute molecules into distinct solvated parts, which is electrolytic dissociation. The effect in either case is to reduce greatly the fugacity of the solute,  $p$ , and hence to give strongly negative deviations from Raoult's law. On the other hand, if electrical conductivity is being investigated, it would make a great deal of difference whether or not such dissociation took place, for only then would the ions be free to migrate. This point of view may serve to explain the difference in the values for the degree of dissociation obtained by thermodynamic and by conductivity methods. It is probably folly to expect them to agree, just as it doubtless is folly to expect the different methods for determining the "association factor" of polar liquids to agree.

(f) **Metallic Solutions.**—Here again, our meagre knowledge of the substances in the liquid state prevents any such comparisons as were made earlier. We have discussed previously the probable relative values of the internal pressures of molten metals.

There are many pairs of metals not completely miscible in the liquid state, corresponding to large positive deviations from Raoult's law. These pairs are in accord with what little basis we have at present for prediction. The following examples may be cited: iron-lead, copper-lead, bismuth-iron, aluminum-sodium, chromium-tin, nickel-thallium.

On the other hand, metals near together in the above respects mix readily; giving solid solutions, in many cases, indicating close approximation to Raoult's law in the liquid phase. Examples are silver-gold, bismuth-copper, cadmium-mercury, nickel-cobalt, iron-manganese.

### 5. Summary.

1. The following conclusions can be drawn when Raoult's law holds for a mixture of two liquids:

(a) The solubility of a vapor or gas in terms of its mol-fraction in the solution is given by  $p/P$ , the ratio of the partial pressure of the gas to its saturation pressure. The latter may have to be gotten by extrapolation above the critical pressure.

(b) The solubility of a solid in terms of mol-fraction is given by the ratio of the vapor pressures of its solid and liquid forms at the temperature in question. This can be calculated from the heat of fusion and the melting point, and will be smallest for solids having a high melting point and a large heat of fusion.

(c) When solubility is expressed as weight of solute in a given weight of solvent, the solubility, other things being equal, will be greatest for

solutes of high molecular weight, and for solvents of low molecular weight. When the solubility is expressed as amount of solute in a given volume of the solvent, it is greatest for solvents having low molecular weight and high density.

(2) Deviations from Raoult's law may be ascribed primarily to inequality of internal pressure and to polarity. These factors, and their approximate prediction, have been discussed at some length for various kinds of liquids.

(a) Nonpolar liquids having approximately equal internal pressures obey Raoult's law, and are subject to the previous generalizations.

(b) A difference in internal pressure, with nonpolar liquids, produces a positive deviation from Raoult's law for both components, decreasing the solubility, whether considered with respect to a gaseous or a solid form of the component in question. Very great differences in internal pressure are necessary for incomplete miscibility of the two components in the liquid form.

(c) A polar and a nonpolar liquid show strong positive deviations from Raoult's law, with accompanying effects on solubilities. Most liquids which are not completely miscible belong to this class.

(d) Two polar liquids may show either positive or negative deviations from Raoult's law, usually positive where there is considerable difference in polarity, and negative when both are highly polar. The effects on solubility correspond to the direction of these deviations.

Numerous examples are given justifying the points of view presented.

## AN ADIABATIC CALORIMETER.

BY FARRINGTON DANIELS.

Received May 2, 1916.

The cooling correction, which is essential in ordinary calorimetry, is troublesome and uncertain. The adiabatic calorimeter as devised by Richards eliminates this correction, but since it has not received the general acceptance which, in the opinion of the author, it deserves,<sup>1</sup> an attempt has been made in this laboratory to modify the construction so as to bring it into more popular favor. Electrolytic heating, as used by Derby, has made possible the development of a calorimeter which it is hoped will accomplish this purpose.

In common calorimetric practice the temperature is read at frequent intervals and the correction for radiation is calculated by one of several

<sup>1</sup> See criticisms of Dickinson, Bureau of Standards, *Bull.* 11, 206 (1914), and of Jaeger and von Steinwehr, *Z. physik. Chem.*, 54, 428 (1906).

formulae, the best of which is that of Regnault-Pfaunder.<sup>1</sup> Even this is open to objection except for small temperature changes. For commercial work its use entails too much labor, and simpler but less accurate approximations are employed. The simplest method of eliminating radiation is that which employs a vacuum jacketed calorimeter. This is wholly satisfactory in many cases but conduction through the glass may introduce a large and ill-defined heat capacity and if the temperature is not close to that of the room, appreciable exchange of heat with the environment does take place. Furthermore, at high temperatures, condensation of vapor on the cooler cover and upper walls may introduce considerable errors from evaporation.

These difficulties are overcome in the adiabatic calorimeter of Richards, which has been used in the extensive thermo-chemical investigations of high precision at Harvard University.<sup>2</sup> It is so arranged that the temperature of an outer jacket is raised at a rate equal to the rate of rise in the calorimeter. Thus there can be no exchange of heat with the environment. The outer jacket is filled with a strong solution of sodium hydroxide and sulfuric acid is added from a buret as needed, to keep the two temperatures always equal.

The use of strong alkali, however, is objectionable as well as expensive and electrical heating coils may be used instead, as suggested in Richards' first paper. Benedict and Higgins<sup>3</sup> described such a calorimeter in which there was a lag of nearly a minute, necessitating preliminary experiments and giving a determination adiabatic to only about  $0.1^{\circ}$ . Slevenski and Pakovitch<sup>4</sup> have appreciated the advantages of the adiabatic calorimeter. They filled an outer jacket with kerosene and heated it with coils of iron wire of special design. Their results are satisfactory although they are able to keep the process adiabatic to only  $0.1^{\circ}$  or  $0.2^{\circ}$ . In work with Professor Richards, as yet unpublished, the author used a small calorimeter in which a heating coil of nichrome wire was placed in an outer bath of oil. Fifteen seconds were usually required after closing the electrical circuit before the Beckmann thermometer was affected. This time lag was troublesome, but with a slow and regular rise the determination could be kept adiabatic to within  $0.02^{\circ}$  with the help of a rheostat and a previous calibration.

<sup>3</sup> *THIS JOURNAL*, 32, 461 (1910).

<sup>4</sup> *J. Russ. Phys. Chem. Soc.*, 46, 1284 (1914). These authors have criticized the descriptions of Richards' calorimeter as being inadequate but the details concerning stirring and adiabatic control for which they searched may be found in the works already cited (*THIS JOURNAL*, 32, 447-450 (1910)), for example.

For rapid or irregular rises electric heating with coils is wholly inadequate and it becomes necessary to eliminate the time lag. Dr. Derby has shown how this can be done in electrolytically heated thermostats<sup>1</sup> and the application to adiabatic calorimeters is obvious. By making the whole water jacket itself the conductor, its temperature rises instantly and uniformly throughout with the passage of the current. In this way it is not necessary to wait for a resistance wire to heat up before the temperature of the bath rises, and rapid stirring becomes unimportant for the heat is not localized.

The construction of a calorimeter along these lines is a simple matter. The one which is shown in Fig. 1 has been in successful operation in this laboratory for over a year, and because it embraces some new features, a brief description is offered. The inner can, A, of thin copper, is filled with water (about half a liter). It contains the source of heat, B, which may be, for example, a combustion bomb or an electric heating coil. It is set into a slightly larger vessel, C, and supported on short pieces of very fine glass tubing so that there is everywhere an air gap of half a centimeter between the walls. Three of these glass supports are soldered to the bottom and six to the sides.<sup>2</sup> A brass collar, D, is soldered to the vessel C, and it is tapered so that a brass cover, E, sets down into it snugly as a ground-glass stopper fits into its bottle. This ring and cover are easily turned out by any machinist in a few hours and ground with emery to give a water-tight joint. Various types of screw covers and rubber rings were tried, but none approached this in simplicity of operation and absolute protection from leakage. The inner vessel is plated with silver and the outer one with nickel, except at the ground joint. They

Fig. 1.

<sup>1</sup> THIS JOURNAL, 35, 1767 (1913).

<sup>2</sup> Glass may be soldered to metal readily if it is first roughened with a file or with hydrofluoric acid, platinized and then copper plated.

are supported in a large copper vessel, F, by nine glass tubes G fitting snugly over short brass rods soldered to it. A still larger vessel H, and a packing, I, of insulating material (kieselguhr) diminish the radiation. A stirrer, J, of the propeller type with four blades bent into the form of a screw is driven by a small water motor. A small, semicircular compartment opens from the vessel F, and the stirrer is so placed that half of its revolution is made in the main part of the jacket and half in the compartment.

This arrangement gives a rapid circulation around the sides of the calorimeter and over and under it. The two vessels C and F are connected with the terminals of a 110-volt, alternating current through a knife switch so that the current may be passed directly through the water of the jacket. The stirrer K in the inner can is similar to J, but much smaller. It revolves in a metal sheath which is insulated from the cover by glass tubing. All tubes leading into the calorimeter, whether of glass or of metal, are soldered to the cover and there is, accordingly, no danger from leakage. In order to cut down the space into which the liquid can vaporize, a thin strip of mica is wired around the top of the can, A, and projects above it so as to touch the cover. With this arrangement, liquid can not evaporate to fill the air space at the sides and bottom, but only at the top.

In most adiabatic calorimetry two thermometers have been used; one in the calorimeter and one in the jacket. Rapid readings entail a considerable strain on the observer, so a thermocouple, L, is substituted for them, thereby simplifying the manipulation and increasing the accuracy.<sup>1</sup> The filament of an ordinary tungsten light or a Nernst lamp is focused through a reading lens to a galvanometer and thence to a ground-glass scale or a white paper scale in a dark box. The thermocouple consists of eight copper-constantan junctions packed in paraffin and enclosed in a tapering sheath of very thin glass.<sup>2</sup> The galvanometer (type P as manufactured by Leeds and Northrup) is placed about five meters from the scale and calorimeter. A difference in temperature of  $0.01^{\circ}$  between the inner can and the jacket gives then a deflection of about 1 cm. which may be read without difficulty at a considerable distance.

When the outer jacket is too cold the switch is closed, the alternating current passes through the water of the jacket and the temperature rises instantly. When the thermocouple registers zero the switch is opened and the heating ceases almost at once. With a slow rise of  $0.2^{\circ}$  per minute, or less, it is easy to keep the temperature of the jacket always within  $0.01^{\circ}$  of the temperature of the calorimeter. With a rapid rise of  $1^{\circ}$  per minute the process may be kept adiabatic to within 0.02 or 0.03.

<sup>1</sup> Dickinson has used a thermocouple in an adiabatic calorimeter, Bureau of Standards, *Bull.* 11, 242 (1914).

<sup>2</sup> See White, *THIS JOURNAL*, 36, 2300 (1914) and Adams, *Ibid.*, 37, 484 (1915).

The following test was made, in which the inner liquid was heated intermittently with an electric heating coil so as to obtain an irregular rise. A boy of high school age, after fifteen minutes' practice, watched the thermocouple scale and controlled the switch, while a second observer recorded the temperature of the calorimeter as registered on a thermometer, and the difference between it and the temperature of the jacket as registered by the thermocouple.

Time.		Temperature calorimeter.	Temperature jacket.	Time.		Temperature calorimeter.	Temperature jacket.
Minutes.	Seconds.			Minutes.	Seconds.		
0	0	28.25	-0.01	1	45	30.20	+0.01
0	15	28.60	$\pm 0.00$	2	00	30.50	+0.03
0	30	28.80	-0.02	2	15	30.60	-0.00
0	15	28.90	$\pm 0.00$	2	30	30.80	-0.05
1	00	29.20	-0.01	2	45	31.20	-0.01
1	15	29.40	-0.03	3	00	31.40	$\pm 0.00$
1	30	29.80	-0.02				

The limits of error allowable in the adiabatic control were determined experimentally. It was found that if the temperature of the jacket differed from the temperature of the calorimeter by  $0.1^\circ$  an exchange of heat took place at the rate of 0.5 calorie per minute. If the difference was  $0.01^\circ$ , the heat transfer was 0.05 calorie per minute. This value is of the same order as that found by Richards and Burgess and by Slevenski and Pakovitch in adiabatic calorimeters of larger dimensions. If there is a continuous error of  $0.01^\circ$  in the adiabatic regulation of a calorimeter holding 1 liter an error of 0.01% would be introduced in a determination lasting ten minutes where there was a rise of  $5^\circ$ . Since large errors in the adiabatic control exist but momentarily and since positive and negative differences tend to cancel each other it is safe to say that in the calorimeter described above the AVERAGE difference between jacket and calorimeter may be kept less than  $0.01^\circ$ . This difference could be made smaller by using a more sensitive galvanometer or by increasing the number of junctions in the thermocouple.

With the beam of light from the thermocouple circuit swinging back and forth, the next advance was the automatic control of the heating circuit by means of a selenium cell.<sup>1</sup> The general plan is shown in Fig. 2. When the jacket and the calorimeter are at the same temperature the thermocouple gives a zero reading, and the light rests on the selenium cell, thereby lowering the resistance and closing the relay which breaks the 110-volt heating current. When the calorimeter heats up a little the beam of light moves off from the selenium cell, the relay opens and the heating circuit is closed. The selenium cell is readily made<sup>2</sup> in a few

<sup>1</sup> The use of a selenium cell in such a connection had been suggested in conversation by Mr. A. T. Larson of Harvard University.

<sup>2</sup> See *Sci. Amer. Supplement*, Jan. 27 (1912).

hours from a strip of mica which is notched and wound with No. 32 copper wire. Two wires are used, one starting from each end, and they are wound on alternate notches. These wires are not in electrical contact except through the very large surface of selenium which fills the spaces

Fig. 2.

used in this circuit is very small and about ten volts from dry cells or small storage batteries are sufficient. A powerful relay of 150 ohms is essential, and to prevent a slight sticking of the contacts, it is vibrated gently by a rod which projects from the stand which holds the pulley wheels. Since the movement of the armature is small, the 110-volt circuit can not be used with it directly, for sparking is too great. Accordingly a second cheap relay is operated by a dry cell through the first relay and it in turn controls the heavy current. Occasionally with a rapid rise the beam of light swings beyond the selenium cell and on to the wrong side, upsetting the whole adiabatic control. To prevent this a stout wire is fastened to the galvanometer box in such a way that the mirror is arrested when the jacket becomes too hot. The tension on the spring of the relay requires frequent adjustment but for a slow rise the determination may be kept adiabatic to within  $0.02^\circ$  or  $0.03^\circ$  without attention.

between them. The selenium powder is spread on the cell, heated to its melting point and molded into place between the wires with a hot glass rod, cooled, and annealed for eight hours at  $215^\circ$  C. A rather large cell (3 cm.  $\times$  20 cm.) and a broad, bright beam of light are desirable. A Nernst lamp with a small convex lens gives an excellent light at a distance of five meters. The selenium cell is placed at the end of a long, black box to cut out the entrance of all light except that from the galvanometer mirror. The current

This synthermal regulator has advantages over that of Richards and Osgood<sup>1</sup> in that it is small and can be attached readily to any calorimeter without inconvenience. The fact that it requires a galvanometer and a good relay is an objection. Because the regulation by hand is such a simple matter, this selenium cell regulator is not recommended for common calorimetric practice unless a large number of determinations are to be made.

It is by no means difficult to alter an ordinary calorimeter so as to make it adiabatic and in fact some of the well-known calorimeters on the market are already surrounded by water jackets. By cutting the two cans apart, inserting glass supports, and attaching a tight cover, one would have an apparatus similar to the one shown in Fig. 1. Hand stirrers could be used to advantage. Even for very rough work it is worth while to eliminate the cooling correction. The water-tight cover may be omitted and a cheap galvanometer is sufficiently sensitive. The stirrer is unnecessary for the temperature in different parts of the jacket does not vary by more than  $0.5^{\circ}$ . Experiments with a crude calorimeter constructed in this way showed a cooling effect of  $0.08^{\circ}$  in ten minutes for a five-degree elevation, whereas under the same conditions without this simple jacket the cooling effect was  $0.37^{\circ}$ . The rate at which the jacket is heated may be very rapid but then the adiabatic control becomes more difficult. If the current is limited to 6 amperes by a fuse plug, 10,000 calories  $\frac{(110 \times 6 \times 60)}{4.18}$  per minute can be introduced, giving a rise of  $5^{\circ}$  per minute with the calorimeter described in Fig. 1. No ordinary calorimetric measurements would require that the jacket be heated up as fast as this. With pure water in the jacket the resistance is high and the heating correspondingly slow but small amounts of electrolyte diminish this resistance greatly. The amperage should be adjusted by the addition of dilute copper sulfate solution so that the rise in the jacket is appreciably more rapid than the most rapid rise in the calorimeter.

Corrosion with an alternating current is not great although the conductivity of the jacket becomes greater and greater, so that the solution must be changed at intervals. If the vessels become seriously corroded they may be renewed by electroplating.

By substituting a high-boiling liquid for water the range of the calorimeter may be extended beyond  $100^{\circ}$ . When a solution of ferric chloride in glycerol fills the jacket the calorimeter may be used up to  $200^{\circ}$ . In case the glycerol is pure it must be heated first as such a solution is a poor conductor at room temperatures. Experiments have shown that the adiabatic control here is just as satisfactory as with the aqueous solutions.

<sup>1</sup> THIS JOURNAL, 37, 1718 (1915).

Professor Derby has suggested (in conversation) the use of fused salts for electrolytically heated thermostats at much higher temperatures, and the same idea could be applied to calorimetry. In fact the use of such a calorimeter should open up a whole new field to accurate physical-chemical measurements.

### Summary.

In conclusion it may be said that adiabatic calorimeters eliminate cooling corrections, thereby excluding errors from precision work and saving time in commercial work. They permit a slow and careful reading of a thermometer while the temperature is constant, and the taking of temperature before and after a determination becomes unnecessary.

Errors from evaporation are negligible in the Richards type of calorimeter or in the modification described in this article, as there is no colder matter in contact with the vapor; and heat can not be lost or gained from the room by conduction. For high temperatures, for slow reactions, or for large temperature differences, these calorimeters are absolutely necessary.

The description of an adiabatic calorimeter of new design is given and it has proved to be accurate and simple of operation.

The automatic control of this calorimeter by means of a selenium cell has been successful, and this very sensitive relay may find application in other work:

The calorimeter herein described is being used in this laboratory in the accurate determination of the specific heats of salt solutions and of organic liquids.

## THE SPECIFIC CONDUCTIVITY OF PURE WATER IN EQUILIBRIUM WITH ATMOSPHERIC CARBON DIOXIDE.

BY JAMES KENDALL.

Received May 20, 1916.

CONTENTS.—1. Introduction. 2. Previous Work. 3. The Ionization Constant of Carbonic Acid. 4. The Heat of Ionization of Carbonic Acid. 5. The Velocity of the Hydrogen Carbonate Ion. 6. The Carbon Dioxide Content of the Atmosphere. 7. The Solubility of Carbon Dioxide in Water. 8. The Specific Conductivity of the Saturated Solution. 9. Summary.

### 1. Introduction.

The evaluation of the specific conductivity of pure water in equilibrium with the carbon dioxide of the atmosphere is a problem which is of especial importance in connection with the water correction in conductivity determinations.<sup>1</sup>

<sup>1</sup> This subject will be discussed fully in a forthcoming communication.

Carefully prepared conductivity water, when in contact with air, has been found by many observers<sup>1</sup> to possess a constant specific conductivity of  $0.7-0.8 \times 10^{-6}$  reciprocal ohms at the ordinary temperature (usually  $18^\circ$ ). Considering the different methods of preparation employed by different investigators in different laboratories, the numerous values recorded in the literature are remarkably uniform. Whatever method may have been followed and however small the specific conductivity of the water obtained may be when first prepared, its value rises rapidly, on standing, to the limits indicated above, and then remains practically constant.

The suggestion has frequently been made that the conducting impurity in such samples of water consists almost entirely of carbonic acid derived from the atmosphere.<sup>2</sup> It is of interest, therefore, to test whether the *directly-determined* experimental value for the specific conductivity of water in contact with air is in agreement with the value which may be calculated *indirectly* with the help of the following data:

- (a) The ionization constant of carbonic acid.
- (b) The mobility of the hydrogen carbonate ion,  $\text{HCO}_3^-$ .
- (c) The carbon dioxide content of the atmosphere.
- (d) The solubility of carbon dioxide in water.

Concordance between the observed and calculated values will obviously support strongly the validity of the above suggestion.

The figures at present available, however, for such a calculation are only approximate and incomplete. It is the purpose of this paper to establish exact values for all of the quantities tabulated above at  $0^\circ$ ,  $18^\circ$  and  $25^\circ$ , the three temperatures most generally employed in conductivity investigations. It may also be mentioned that an accurate knowledge of these quantities is of some importance apart from the present problem, since their use is essential in many geological studies and in questions of interest in various other fields.<sup>3</sup>

## 2. Previous Work.

The problem has already been taken up, for the temperature of  $18^\circ$ , in the researches of Knox<sup>4</sup> on the conductivity of carbonic acid solutions

<sup>1</sup> A complete list of references will be found in the succeeding article.

<sup>2</sup> See especially Kohlrausch and Holborn, "Leitvermögen der Electrolyte," p. 111 (Leipsic, 1898); Walker and Cormack, *J. Chem. Soc.*, 77, 5 (1900); and Arrhenius, *Meddelanden från K.-Vet. Akads. Nobelinstitut*, Band 2, No. 42 (1914).

<sup>3</sup> For example, see R. C. Wells, *J. Wash. Acad. Sci.*, 5, 617 (1915); Johnston, *THIS JOURNAL*, 38, 947 (1916); Walker and Kay, *J. Soc. Chem. Ind.*, 31, 1013 (1912); Arrhenius, *Phil. Mag.*, 41, 237 (1896).

<sup>4</sup> Knox, *Ann. der Physik.*, 54, 44 (1895). The figures given in this and all succeeding references have (where necessary) been recalculated from Siemens' units to units of the reciprocal ohm.

and of Walker and Cormack<sup>1</sup> on the dissociation constants of very weak acids.

The conductivity measurements of Knox, as will be shown in a later section of this paper, are obviously considerably in error; the method employed by him for the calculation of the solubility of carbon dioxide in water under atmospheric conditions is also inaccurate. Consequently, his conclusion that the calculated value for the specific conductivity of water in equilibrium with the carbon dioxide of the atmosphere ( $0.60 \times 10^{-6}$  reciprocal ohms at  $18^\circ$ ) is substantially identical with the direct experimental value of Kohlrausch and Heydweiller<sup>2</sup> ( $0.64 \times 10^{-6}$  reciprocal ohms at  $18^\circ$ ) is not entirely convincing.

The results obtained by Walker and Cormack are of much greater value. It was found that carefully purified Dundee water (prepared by three successive distillations, namely from alkali, from phosphoric acid, and without the addition of any chemical) possessed a specific conductivity of  $0.75 \times 10^{-6}$  reciprocal ohms at  $18^\circ$ . The ionization constant of carbonic acid at this temperature was found to be  $3.04 \times 10^{-7}$  (a value differing by 20% from that obtained by Knox). The dilution of a solution saturated with carbon dioxide at a pressure of 760 mm. was taken as equal to 24 liters; according to Bunsen's absorption data.<sup>3</sup> Assuming the partial pressure of carbon dioxide in air to be 0.0003 atmosphere,<sup>4</sup> the specific conductivity of water in equilibrium with atmospheric carbon dioxide was calculated to be  $0.70 \times 10^{-6}$  reciprocal ohms at  $18^\circ$ . The agreement of this value with that directly determined is clearly close enough to support the assumption that the specific conductivity of water in contact with air is to be ascribed almost entirely to dissolved carbon dioxide. Further confirmation was found in the results obtained from the application of a correction made under this assumption to the conductivity values of aqueous solutions of phenol.<sup>5</sup> This will be more fully discussed in the following communication.

It must be admitted, however, that the greater part of the data employed by Walker and Cormack in the above calculation is only approximate. In fact, the only exact figure utilized is that for the ionization constant of carbonic acid, and even that differs considerably from the value found by Knox.

In the present paper, therefore, the conductivity measurements of Walker and Cormack for the temperature of  $18^\circ$  have been repeated, and results have also been obtained for two other temperatures— $0^\circ$  and

<sup>1</sup> Walker and Cormack, *J. Chem. Soc.*, 77, 5 (1900).

<sup>2</sup> Kohlrausch and Heydweiller, *Z. physik. Chem.*, 14, 317 (1894).

<sup>3</sup> These results may be in error by several per cent., as may be seen by reference to the original paper, *Ann.*, 93, 1 (1855).

<sup>4</sup> Obviously only a very rough approximation.

<sup>5</sup> Walker and Cormack, *J. Chem. Soc.*, 77, 18 (1900).

25°. Exact determinations have been made regarding the carbon dioxide content of the atmosphere, and more recent and accurate data for the solubility of carbon dioxide in water have been employed in the final calculations. The different steps necessary for the exact solution of the problem are taken up in order below. The summarized results will be found in Section 8.

### 3. The Ionization Constant of Carbonic Acid.

A solution of carbon dioxide in water possesses considerable electrical conductivity, due to the fact that the gas does not exist in solution merely as carbon dioxide, but also combines with the solvent to give the acid  $\text{H}_2\text{CO}_3$ , which ionizes into  $\text{H}^+$  and  $\text{HCO}_3^-$ . The complete equilibrium to be considered<sup>1</sup> is

(The secondary dissociation of  $\text{HCO}_3^-$  into  $\text{H}^+$  and  $\text{CO}_3^{2-}$  is so minute<sup>2</sup> that it need not be taken into consideration here.)

The conductivity of carbonic acid solutions was first investigated by Pfeiffer<sup>3</sup> at temperatures of 0° and 12.5°. Ionization constants were unknown quantities when these measurements were published, and since the results of Pfeiffer, recalculated according to the dissociation theory, have not previously been tabulated, they are summarized in the following table. The first column indicates the dilution of the solution in liters (V); the second the equivalent conductivity<sup>4</sup> ( $\Lambda$ ); the third the dissociation constant  $k$ , multiplied by  $10^7$  to avoid an excess of zeros. Subsequent tables are arranged according to the same scheme.

TABLE I.—CARBONIC ACID (PFEIFFER).

Temperature, 0°.			Temperature, 12.5°.		
V.	$\Lambda$ .	$k \times 10^7$ .	V.	$\Lambda$ .	$k \times 10^7$ .
2.37	0.167	1.68	2.79	0.304	3.18
3.07	0.188	1.65	3.29	0.334	3.25
3.85	0.213	1.69	5.27	0.421	3.23
4.39	0.235	1.81	6.59	0.450	(2.95)?
13.38	0.458	(2.26)?	13.38	0.661	3.14
$\infty$	264.0	..	$\infty$	323.0	..

Whence  $k = 1.7 \times 10^{-7}$

Whence  $k = 3.2 \times 10^{-7}$

The constancy of the values in the last column is by no means all that could be desired at either temperature, and the dissociation constants given are, at best, only approximate values. This is probably due to the poor quality of water (specific conductivity =  $3.2 \times 10^{-8}$  reciprocal ohms) employed in the investigation; the conducting impurities present

<sup>1</sup> The discussion of this equilibrium is deferred to a later section; see page 1493.

<sup>2</sup> McCoy, *Am. Chem. J.*, 29, 437 (1903); Johnston, *THIS JOURNAL*, 37, 2001 (1915).

<sup>3</sup> Pfeiffer, *Ann. Phys.*, 23, 625 (1884).

<sup>4</sup> The determination of the equivalent conductivity at infinite dilution ( $\Lambda_\infty$ ), which is necessary for the evaluation of  $k$ , is described in a following section.

might suffice to account for a considerable portion of the measured conductivities.

The measurements of Knox<sup>1</sup> may also be used to calculate the ionization constant of carbonic acid at temperatures of 12.5° and 18°. Knox did not attempt to carry out these calculations himself, in an abstract<sup>2</sup> an erroneous value is given, and Walker and Cormack<sup>3</sup> have given one series of results under the old Siemens units. The complete results of Knox have, therefore, been calculated to modern units and are summarized in Table II, below.

TABLE II.—CARBONIC ACID (KNOX).

Temperature, 12.5°.			Temperature, 18°.		
V.	$\Lambda$ .	$k \times 10^7$ .	V.	$\Lambda$ .	$k \times 10^7$ .
10.48	0.603	3.32	12.61	0.778	3.76
12.24	0.652	3.32	14.54	0.838	3.79
15.43	0.735	3.34	24.9	1.090	3.75
20.79	0.853	3.36	53.2	1.581	3.70
29.77	1.019	3.35	125.0	2.445	3.77
$\infty$	323.0	....	$\infty$	354.0	....
Whence $k = 3.34 \times 10^{-7}$			Whence $k = 3.75 \times 10^{-7}$		

The constancy of the values obtained by Knox appears to be quite satisfactory; the dissociation constant at 12.5° is also in good agreement with that given by the measurements of Pfeiffer. Nevertheless the later results of Walker and Cormack indicate that Knox's measurements also are considerably in error. The cause is again, most probably, the poor grade of water (specific conductivity as high as  $2.8 \times 10^{-6}$  reciprocal ohms) used in the determinations. Thus, at dilution 125 in Table II, the conductivity of the water amounted to 12% of the total conductivity of the solution. For dilutions higher than 125,  $k$  is no longer a constant.

The careful measurements of Walker and Cormack at 18° are recalculated to modern units and given in Table III, below. A column indicating the ratio of the ionized to the total solute,  $[\alpha]$ , is added.

TABLE III.—CARBONIC ACID (WALKER AND CORMACK), 18°.

V.	$\Lambda$ .	$\alpha$ .	$k \times 10^7$ .
27.5	1.033	0.00289	3.05
55.0	1.454	0.00407	3.03
82.5	1.784	0.00500	3.04
110.0	2.052	0.00575	3.02
$\infty$	354.0	...	..

Whence  $k = 3.04 \times 10^{-7}$

The value of the ionization constant is about 20% less than the value calculated from Knox's figures, corresponding to an actual difference in the conductivity of 10%. The better quality of the water used (specific

<sup>1</sup> Knox, *Loc. cit.*

<sup>2</sup> *Z. physik. Chem.*, **17**, 186 (1896).

<sup>3</sup> Walker and Cormack, *J. Chem. Soc.*, **77**, 9 (1900).

conductivity =  $0.75 \times 10^{-6}$  reciprocal ohms) and the fact that a more exact method was employed for measuring the concentration of the solutions<sup>1</sup> cause the investigators to conclude that their own numbers are probably the more accurate.

This conclusion is confirmed by the present author's measurements, which are given in Table IV, below. The experimental method adopted for the conductivity determinations was precisely that followed and described in previous investigations.<sup>2</sup> A Cantor cell<sup>3</sup> (with large electrodes only a small distance apart) was employed, this type possessing the advantage that successive dilutions can be made rapidly and accurately *within* the cell. A rotating commutator and a galvanometer were used in place of the more general induction coil and telephone, and gave satisfactory results throughout. The bridge employed was a three-meter platinum wire with one thousand divisions; readings could be obtained and duplicated to one-tenth of a division at all dilutions, the galvanometer being used as a zero instrument. The cells were immersed when in use in a large electrically-controlled thermostat, the greatest variations in temperature during the observation period being  $0.005^{\circ}$ .

The solutions of carbonic acid were prepared by passing pure carbon dioxide (obtained by the action of tartaric acid<sup>4</sup> on sodium carbonate) first through several wash-bottles containing conductivity water, and finally through the water (60 cc. in volume) contained in the Cantor cell. The water employed possessed a specific conductivity of  $0.60 \times 10^{-6}$  reciprocal ohms at  $0^{\circ}$ ,  $0.75 \times 10^{-6}$  reciprocal ohms at  $18^{\circ}$ , and  $0.85 \times 10^{-6}$  reciprocal ohms at  $25^{\circ}$ . The method of its preparation will be described fully in the following paper.

The concentration of carbonic acid in each solution was determined *immediately after* the conductivity measurements had been completed, by running out half of the volume (30 cc.) from the cell and estimating its carbon dioxide content by a suitable modification of the Walker-Pettenkofer method.<sup>5</sup> The results obtained from duplicate experiments were in agreement within 0.2%.

An examination of the last column of Table IV will show that the ionization constants obtained at each temperature are *true* constants

<sup>1</sup> A modification of Pettenkofer's method; see Walker, *J. Chem. Soc.*, 77, 1110 (1900).

<sup>2</sup> Kendall, *J. Chem. Soc.*, 101, 1275 (1912).

<sup>3</sup> Cantor, *Z. Elektrochem.*, 9, 922 (1903).

<sup>4</sup> If the carbon dioxide is prepared by the action of hydrochloric acid on marble in the usual manner, a trace of hydrochloric acid is invariably carried over into the conductivity cell, in spite of the several intervening wash-bulbs.

<sup>5</sup> Walker, *Loc. cit.* The solution was run directly into a bottle containing air free from  $\text{CO}_2$ , excess of baryta solution of known concentration added, and the normal procedure then followed.

throughout the whole range of dilutions. The value obtained at  $0^\circ$  is much higher than that given by the measurements of Pfeiffer; the value at  $18^\circ$  is in good agreement with that of Walker and Cormack.

TABLE IV.—CARBONIC ACID (KENDALL).

V.	$\Lambda$ .	$\alpha$ .	$k \times 10^7$ .

145.5	2.820	0.00717	3.55
$\infty$	393.4	...	..
Whence $k = 3.50 \times 10^{-7}$			

#### 4. The Heat of Ionization of Carbonic Acid.

The accuracy of the values for the ionization constant of carbonic acid given in Tables I–IV may be tested by calculating, from the figures for two different temperatures, the heat of ionization,  $Q$ , according to the van't Hoff formula

$$\log k_1 - \log k_2 = (Q/2.303 R) (1/T_1 - 1/T_2)$$

(where  $k_1$  and  $k_2$  are the dissociation constants at absolute temperatures  $T_1$  and  $T_2$ , respectively) and comparing the calculated value with that obtained by direct thermal measurements. The heat of the reaction:  $\text{H}_2\text{CO}_3(\text{aq.}) = \text{H}^+ + \text{HCO}_3^-$  is the heat of mixture of one mol  $\text{H}_2\text{CO}_3$  and one mol  $\text{NaOH}$ , less the heat of neutralization of one equivalent of a strong acid. From the measurements of Thomsen<sup>1</sup> it is equal to  $-2800$  cal.

The values for  $Q$  as calculated from the results tabulated above are as follows:

<sup>1</sup> Thomsen, "Thermochemische Untersuchungen," Leipzig (1882).

TABLE V.—HEAT OF IONIZATION OF CARBONIC ACID.

Temperature interval.	Observer.	Heat of ionization.
0°–12.5°	Pfeiffer	—7850 cals.
12.5°–18°	Knox	—3480 cals.
0°–25°	Kendall	—2890 cals.
0°–18°	Kendall	—2910 cals.
18°–25°	Kendall	—2830 cals.

The agreement of the values of the present paper with that directly determined is very satisfactory, the results of Pfeiffer and of Knox, on the other hand, give figures which are far too high.

A careful consideration of the complete equilibrium in carbonic acid solutions, however, introduces a disconcerting factor into the above calculation. The "ionization constants" and "heats of ionization" given in the tables preceding have not the exact signification that is usually attached to those quantities. The equilibrium equation

shows that the nonionized portion of the solute exists partly as  $\text{H}_2\text{CO}_3$  and partly as  $\text{CO}_2$  in the solution. The *true* ionization constant:  $(\text{conc. H}^+)/(\text{conc. HCO}_3^-)/(\text{conc. H}_2\text{CO}_3)$  will therefore be different from (and greater in value than) that calculated in Tables I–IV according to the formula:  $(\text{conc. H}^+)/(\text{conc. HCO}_3^-)/(\text{conc. H}_2\text{CO}_3 + \text{conc. CO}_2)$ . Similarly the *true* heat of ionization will differ from that calculated above, in which the heat of the reaction  $\text{CO}_2(\text{dissolved}) + \text{H}_2\text{O} = \text{H}_2\text{CO}_3$  is also included.

Owing to the fact that the ratio:  $(\text{conc. CO}_2)/(\text{conc. H}_2\text{CO}_3)$  in the solution will not vary with the dilution (providing only dilute solutions are investigated,<sup>1</sup> the "ionization constants" obtained in the above tables still show a constant value, although they are not the *true* ionization constants. The true values could be found from them if the ratio  $(\text{conc. CO}_2)/(\text{conc. H}_2\text{CO}_3)$  at each temperature were known. Unfortunately there does not appear to be any simple way of evaluating this ratio; the conclusion of Walker and Cormack<sup>2</sup> (recently re-expressed by Johnston)<sup>3</sup> that it is less than unity at ordinary temperature is quite devoid of experimental support.<sup>4</sup> In a following section, however, it will be shown that for the purpose of the present investigation the value of the ratio is quite immaterial, since it does not enter into any of the calculations involved.

Only with regard to the heat of ionization does our lack of knowledge concerning the ratio  $(\text{conc. CO}_2)/(\text{conc. H}_2\text{CO}_3)$  cause any confusion here. For if the value of this ratio changes to any great extent within the temperature interval 0–25°, then the heat of hydration:  $-\text{CO}_2(\text{dissolved}) + \text{H}_2\text{O} = \text{H}_2\text{CO}_3$  must be considerable (either positive or negative according

<sup>1</sup> See page 1493.

<sup>2</sup> Walker and Cormack, *J. Chem. Soc.*, 77, 13 (1900).

<sup>3</sup> Johnston, *THIS JOURNAL*, 37, 2003 (1915).

<sup>4</sup> Walker, *J. Chem. Soc.*, 83, 182 (1903).

as the ratio increases or decreases). Heat produced (or absorbed) by this reaction is included in the "heat of ionization" given by the measurements of Thomsen, consequently the *true* heat of ionization may differ considerably from the value of 2800 cal. found by him. Any change in the ratio (conc.  $\text{CO}_2$ )/(conc.  $\text{H}_2\text{CO}_3$ ) within the temperature interval  $0-25^\circ$  also introduces considerable errors into the calculation of the (apparent) "heat of ionization" by means of the van't Hoff equation, as given in Table V. Nevertheless, the fact that these calculated values show satisfactory agreement for *different temperature intervals* with the experimental value of Thomsen indicates that any disturbing factors are only small—*i. e.*, that the heat of hydration is negligible and that the degree of hydration varies but slightly with temperature.

### 5. Velocity of the Hydrogen Carbonate Ion.

In order to obtain the values for  $\Lambda_\infty$  (the equivalent conductivity at infinite dilution) for carbonic acid given in Tables I-IV above, we require to know the velocities of the ions  $\text{H}^+$  and  $\text{HCO}_3^-$  at the temperatures studied.

The velocity of the hydrogen ion at  $25^\circ$  has recently been determined by the present author<sup>1</sup> and found to have the value  $347.2 \pm 0.4$ . With the aid of the temperature coefficient given by Kohlrausch<sup>2</sup> and the tables of Johnston<sup>3</sup> the probable values for the remaining temperatures may be found: at  $18^\circ$ , 313.9; at  $12.5^\circ$ , 288; and at  $0^\circ$ , 239. The accuracy of these values naturally decreases as the extrapolation interval increases, the last value may be in error by 1%.

The velocity of the hydrogen carbonate ion is not so accurately known. From conductivity measurements of sodium hydrogen carbonate solutions, Walker and Cormack<sup>4</sup> deduced the value 40.4 at  $18^\circ$ . Since, however, the highest dilution investigated was 512 liters, the error of extrapolation to infinite dilution might be appreciable.

Conductivity measurements with more dilute solutions of both sodium and calcium bicarbonates at  $25^\circ$  have been described by the author<sup>5</sup> in a previous investigation. The values for  $\text{HCO}_3^-$  obtained from the two series were 46.0 and 46.5, respectively. These figures are rendered only approximate by reason of the grade of the conductivity water employed in the dilutions (specific conductivity =  $1.10 \times 10^{-6}$  reciprocal ohms at  $25^\circ$ ), which exercised a disturbing influence upon the values obtained at high dilutions and necessitated an uncertain correction. The measurements have, therefore, been repeated with a better sample of

<sup>1</sup> Kendall, *J. Chem. Soc.*, 101, 1275 (1912).

<sup>2</sup> Kohlrausch, *Z. Elektrochem.*, 8, 290 (1902).

<sup>3</sup> Johnston, *THIS JOURNAL*, 31, 1010 (1909).

water, the experimental procedure (preparation of the solutions, estimation of their concentration, etc.) being exactly as described in the previous communication. The results are given in the following table:

TABLE VI.—SODIUM AND CALCIUM HYDROGEN CARBONATES. 25°.

NaHCO <sub>3</sub> .		$\frac{1}{2}[\text{Ca}(\text{HCO}_3)_2]$ .	
V.	Λ.	V.	Λ.
12.1	77.3	64	83.3
24.2	81.7	128	88.8
48.4	85.3	256	93.4
96.8	88.2	512	96.7
193.6	90.6	1024	99.6
387.2	92.4	2048	102.0
774.4	93.8	∞	107.7
1548.8	94.8		
3097.6	95.5		
∞	97.1		

The water employed in the dilutions possessed a specific conductivity of  $0.80 \times 10^{-6}$  reciprocal ohms at 25°. No correction has been made in the above values for the water conductivity. That this procedure leads to accurate values for bicarbonate solutions will be seen in the following paper, where it is also shown that the extent and influence of hydrolysis is inappreciable throughout the range of dilutions investigated.

The values for the equivalent conductivity at infinite dilution are derived by graphical extrapolation, according to the method of Bates.<sup>1</sup> Subtracting the figures for the cation of each series ( $\text{Na}^+ = 51.0$  and  $\frac{1}{2}\text{Ca}^+ = 61.4$ ), we obtain the values 46.1 and 46.3, respectively, for the velocity of the hydrogen carbonate ion at 25°. The mean value, 46.2, identical with that previously determined, is employed for the calculation of the velocities for the remaining temperatures, an average temperature coefficient<sup>2</sup> for the ion being assumed. The results obtained are: at 18°, 40.1; at 12.5°, 35; and at 0°, 25. The accuracy of these values is in each case commensurate with that given for the hydrogen ion at the same temperature.

The final values derived for the equivalent conductivity of carbonic acid at infinite dilution are therefore:

At 25°, 393.4; at 18°, 354.0; at 12.5°, 323; at 0°, 264. These are the figures which have been employed in Tables I–IV above.

The ionization data for carbonic acid solutions having now been established, we require to know the concentration of that solution which is in equilibrium with the carbon dioxide of the atmosphere. For this purpose it is necessary to determine two quantities—the carbon dioxide content of the atmosphere and the solubility of carbon dioxide in water.

<sup>1</sup> Bates, *THIS JOURNAL*, **35**, 519 (1913).

<sup>2</sup> Kohlrausch, *Z. Electrochem.*, **14**, 129 (1908).

## 6. The Carbon Dioxide Content of the Atmosphere.

A general impression exists that the carbon dioxide content of the atmosphere is a quantity which, although always very small, varies widely according to the conditions. Among the factors that have been mentioned as producing variations are the following:

(a) *Location*.—Land or sea, country or city, height above the ground, height above sea-level, latitude.

(b) *Time*.—Day or night, season of year, long-periodic changes.

(c) *Weather*.—Rain or fine, foggy or clear, sun or cloud, windy or calm, hot or cold.

(d) *Chance*.—Volcanic eruptions, forest fires, factory fumes, etc.

The actual effect of most of these influences is still uncertain.<sup>1</sup>

If large variations do constantly occur, then obviously it will be impossible to calculate standard values for the specific conductivity of pure water in contact with air, since the concentration of the saturated solution will vary considerably with the conditions. Nevertheless the fact that the experimentally-obtained values of different investigators in different laboratories check so remarkably closely suggests that, even in a laboratory atmosphere, any variations are in general only of minor importance.

The question of the difference between a normal out-door atmosphere and a laboratory atmosphere may first be considered. In this connection, the extensive researches of Benedict<sup>2</sup> on the oxygen content of the atmosphere afford some interesting evidence. The normal carbon dioxide content of outdoor air was found by him to be 3.1 parts in 10,000 by volume (mean of 212 analyses). Even in the Grand Central subway station of New York City, during a rush hour, the value is only doubled—6.1 parts in 10,000. Observations on the air of a crowded business street in Boston showed only the slightest trace of an increase. Hence in a well-ventilated laboratory the divergence from the normal out-door value should obviously not be excessive.

With regard to the influence of location, etc., the following quotation from a memoir by Letts and Blake<sup>3</sup> is, in view of the exhaustive nature of their tabulations, quite decisive: "It must be granted that the *average amount* of atmospheric carbonic anhydride is much the same under the most diverse conditions of weather, locality, season, etc. But on the other hand, there can be no doubt that variations in the amount do occur. These variations, if small in actual amount, are *relatively* large, and correspond with fluctuations of at least 10% of the total quantity."

<sup>1</sup> Letts and Blake, *Proc. Roy. Soc. Dublin*, 9, 107-270, 436-453 (1900).

<sup>2</sup> Benedict, "The Composition of the Atmosphere," *Publ. Carnegie Inst. Wash.*,

1912.

<sup>3</sup> Letts and Blake, *Loc. cit.*, pp. 173-4.

The present author is fortunate in being able to give direct experimental results on this important part of the problem from four laboratories situated in widely-separated localities: Edinburgh, Petrograd, Stockholm and New York City. The figures obtained are in entire agreement with the conclusions of Letts and Blake, the extreme variation in any one laboratory being  $\pm 5\%$  and for the whole range of observations being  $\pm 10\%$ . Conditions were kept as nearly constant as possible by working in large, well-ventilated rooms which contained no gas flames and were not employed for any other chemical work at the same time. The experimenter was the only person in the room and carefully abstained from smoking until determinations were completed.

Several methods were attempted for the estimation of carbon dioxide but the only simple procedure to afford rapid and consistent results was the Walker modification of the Pettenkofer method.<sup>1</sup> This gave values for the carbon dioxide content of the atmosphere which, as checked by duplicate measurements and by blank experiments, were found to be accurate to less than 0.1 part in 10,000 of the total volume. For a description of the experimental procedure and for the method of calculating the results the original paper of Walker should be consulted.

The results obtained are summarized in the following table. The values are expressed as parts of carbon dioxide in 10,000 parts by volume of air, without correction for moisture. They consequently represent partial pressures of carbon dioxide, in atmospheres multiplied by  $10^{-4}$ .

TABLE VII.—CARBON DIOXIDE CONTENT OF THE ATMOSPHERE.

Laboratory.	Time.	Number of deter- minations	Carbon dioxide. Vols. per 10,000.		
			High.	Low.	Average.
University of Edinburgh.....	March, 1911	18	3.88	3.56	3.69
Technological Institute, Petrograd...	Jan., 1913	10	3.80	3.51	3.65
Nobel Institute, near Stockholm....	June, 1913	8	3.56	3.21	3.29
Columbia University.....	July, 1915	24	3.52	3.26	3.39
		60	3.88	3.21	3.53

From an inspection of the above figures it will be evident that the variations are within the limits indicated by Letts and Blake, the greatest divergence from the final mean value—out of a total of sixty determinations—being a little less than  $\pm 10\%$ . If the results for any one laboratory only are considered, the maximum variation is in the region of  $\pm 5\%$ .

Such fluctuations are, in fact, only what may be looked for under the circumstances. The experimental method is accurate to less than 0.1 part in 10,000 of the total volume, but this represents an error of  $\pm 3\%$  in the carbon dioxide content. The tension of the water vapor in the atmosphere at the ordinary temperature of  $20^\circ$  may vary between 0 mm.

<sup>1</sup> Walker, *J. Chem. Soc.*, 77, 1110 (1900); see also Letts and Blake, *Loc. cit.*, pp. 219-229.

and 17.5 mm., *i. e.*, about 2% of the total atmospheric pressure, and since the results in Table VII are not corrected for moisture,<sup>1</sup> this involves a corresponding variation of 2% in the carbon dioxide content. The variations in the results for any one laboratory are thus practically accounted for. The larger variations in the mean value for different laboratories are in all probability due rather to small locality influences than to differences of ventilation. Thus the higher values at Edinburgh and Petrograd may be explained by the fact that the university buildings are situated in each instance near the center of the city. The Nobel Institute, on the other hand, lies out in the country several miles from Stockholm and the laboratories at Columbia are exposed to the fresh breezes across the Hudson<sup>2</sup> even in July.

As legitimately-comparable values of another observer, the results of Letts and Blake for the carbon dioxide content of "air collected in a large unused room in Queen's College, Belfast, with open windows and free circulation" may be quoted.<sup>3</sup> A total of twenty-three determinations shows the following values (expressed in parts per 10,000 by volume and not corrected for moisture): high, 3.73; low, 3.28; mean, 3.49; maximum variation,  $\pm 7\%$ .

It is evident, therefore, that the carbon dioxide content of the atmosphere of a well-ventilated laboratory, unused for other chemical work, is in all normal cases near to the average value of 3.53 parts in 10,000 by volume given in Table VII above. The deviations *may* amount to  $\pm 10\%$ . The fact may be pointed out at once, however, that such deviations will in no way vitiate the conclusions drawn in the following sections of this paper. A variation of 10% in the partial pressure of carbon dioxide involves, indeed, a variation of only 5% in the specific conductivity of the solution in equilibrium with the gas.<sup>4</sup> Variations of this magnitude are found in the observed values, as will be seen later.

In view of the relatively large errors that have been mentioned, it would be difficult to obtain a "standard value" for the carbon dioxide content of the atmosphere to a much higher degree of accuracy than the above, even if that content were (as it certainly is not) a true constant. The fact that exceedingly large variations (as much as 700%) have been recorded by numerous observers is probably due to the faulty methods of estimation that have been generally employed. The most careful and

<sup>1</sup> In order that the values shown may represent actual partial pressures of carbon dioxide.

<sup>2</sup> Also, at times, to the acid fumes from the New Jersey factories. When these were present in quantity, it was necessary to defer experimental work until the wind changed to another quarter.

<sup>3</sup> Letts and Blake, *Loc. cit.*, pp. 136-138.

<sup>4</sup> The specific conductivity varies as the square root of the partial pressure; see the following section.

recent analyses of pure out-door air indicate relatively constant values. Unfortunately most of the observations on record have been obtained in connection with nonchemical investigations, and these frequently betray the fact that at least a little knowledge of chemistry would have been of great assistance to the experimenter, both in the choice of a method and in the execution of the necessary manipulations.

### 7. The Solubility of Carbon Dioxide in Water.

The old and approximate absorption data of Bunsen<sup>1</sup> may be discarded in favor of the more recent and accurate determinations of Bohr and Bock<sup>2</sup> and of Just.<sup>3</sup> Bohr and Bock obtained the following solubility values for the temperatures considered in this paper:

	Absorption coefficient.	Solubility in g. mols per liter.
0°	1.713	0.0764
18°	0.928	0.0414
25°	0.759	0.0338

The second column indicates the number of volumes of carbon dioxide (reduced to 0° and 760 mm.) absorbed by one volume of water at the given temperature when the partial pressure of the gas is one atmosphere (760 mm. Hg). In the third column the concentration of the saturated solution under the same conditions is shown. The values of Just are in close agreement with these.

From the above figures the concentration of the saturated solution under atmospheric conditions (carbon dioxide 3.53 parts in 10,000 by volume) can be calculated. It may be noted that variations in the atmospheric pressure—which may amount to about 3% of the total pressure, affecting the partial pressure of carbon dioxide in the same ratio—may be neglected in this calculation, owing to the greater uncertainty in the "standard value" of 3.53 parts in 10,000 for the carbon dioxide content of the atmosphere. The deviations of carbon dioxide from Boyle's law for pressures below atmospheric<sup>4</sup> may also be left out of consideration for the same reason. The partial pressure of carbon dioxide in the air may therefore be taken as equal to  $760 \times 3.53 \times 10^{-4}$  mm. Hg.

Henry's law in its simple form cannot be employed in our calculations, since at the high dilutions involved the degree of ionization of carbonic acid becomes considerable. It is here that Knox<sup>5</sup> and others have gone astray in estimating the concentration of the solution in equilibrium with the atmosphere. The complete equilibrium series:

<sup>1</sup> Bunsen, *Ann.*, 93, 1 (1855).

<sup>2</sup> Bohr and Bock, *Ann. Physik*, 44, 318 (1891).

<sup>3</sup> Just, *Z. physik. Chem.*, 37, 342 (1901).

<sup>4</sup> See Washburn, "Principles of Physical Chemistry," pp. 30-31 (1915).

<sup>5</sup> Compare Walker and Cormack, *J. Chem. Soc.*, 77, 12 (1900).

leads for dilute solutions<sup>1</sup> to the equations

conc.  $\text{CO}_2$  (in air) =  $k_1$  conc.  $\text{CO}_2$  (dissolved) =

$$k_2 \text{ conc. } \text{H}_2\text{CO}_3 = k_3 \text{ conc. } \text{H}^+ \cdot \text{conc. } \text{HCO}_3^-,$$

in which  $k_1$ ,  $k_2$  and  $k_3$  are constants for any given temperature. The fact that the nonionized solute exists partly as  $\text{CO}_2$  and partly as  $\text{H}_2\text{CO}_3$  does not complicate our calculations at all, since, as will be seen from the above equations, the ratio: (conc.  $\text{CO}_2$ )/(conc.  $\text{H}_2\text{CO}_3$ ) in dilute solutions will be a constant,  $k_2/k_1$ . The series of equilibria therefore simplifies to the following relationships:

(1)  $p/C_u = \text{constant}$ ; where  $p$  is the partial pressure of  $\text{CO}_2$ ,  $C_u$  the concentration of the *total* nonionized solute.

(2)  $C_i^2/C_u = \text{constant}$ ; where  $C_i$  is the concentration of the ionized solute.

These may be further condensed into the simple equation:  $C_i^2/p = \text{constant}$ , whence it follows that *the specific conductivity of a solution of carbonic acid is proportional to the square root of the partial pressure of carbon dioxide under which it exists*. The specific conductivities of the solutions in equilibrium with the air, in which the partial pressure of  $\text{CO}_2$  is  $3.53 \times 10^{-4}$  atmospheres, can therefore readily be obtained for the three temperatures of  $0^\circ$ ,  $18^\circ$  and  $25^\circ$  by combination of the results of Table IV with those of the present section.

For purposes of comparison, the complete solubility and ionization values for these temperatures, under partial pressures of  $\text{CO}_2$  of 1 atmosphere and  $3.53 \times 10^{-4}$  atmospheres, respectively, are given in Tables VIII and IX below. All concentrations are expressed in mols per liter.

TABLE VIII.—SOLUBILITY OF  $\text{CO}_2$  IN WATER ( $p = 1 \text{ ATM.}$ ).

T.	Conc. "total non-ionized" solute.	Conc. ionized solute.	Total concentration.	% ionization.
$0^\circ$	$7.63 \times 10^{-3}$	$1.3 \times 10^{-4}$	$7.64 \times 10^{-3}$	0.16
$18^\circ$	$4.13 \times 10^{-3}$	$1.1 \times 10^{-4}$	$4.14 \times 10^{-3}$	0.26
$25^\circ$	$3.37 \times 10^{-3}$	$1.1 \times 10^{-4}$	$3.38 \times 10^{-3}$	0.33

TABLE IX.—SOLUBILITY OF  $\text{CO}_2$  IN WATER ( $p = 3.53 \times 10^{-4} \text{ ATM.}$ ).

T.	Conc. "total non-ionized" solute.	Conc. ionized solute.	Total concentration.	% ionization.
$0^\circ$	$2.69 \times 10^{-3}$	$2.46 \times 10^{-6}$	$2.94 \times 10^{-3}$	8.4
$18^\circ$	$1.46 \times 10^{-3}$	$2.13 \times 10^{-6}$	$1.67 \times 10^{-3}$	12.8
$25^\circ$	$1.19 \times 10^{-3}$	$2.05 \times 10^{-6}$	$1.40 \times 10^{-3}$	14.7

It will be seen that the concentration of the nonionized portion of the solute decreases rapidly as the temperature rises. In the case of the ionized portion, however, the decrease is but slight, the diminution in the

<sup>1</sup> Where the partial pressure of carbon dioxide is small and the concentration the water in the solution has not been changed appreciably by the addition of the solute.

solubility being almost counterbalanced by the increase in the ionization constant. The last column shows that the degree of ionization of the saturated solution under atmospheric conditions is considerable.

### 8. The Specific Conductivity of the Saturated Solution.

The specific conductivity of pure water in equilibrium with atmospheric carbon dioxide at the temperatures of 0°, 18° and 25° can be calculated directly from the above tables. It may be noted that the specific conductivity of the water itself under these conditions becomes quite negligible in view of the relatively large hydrogen-ion concentration of the solute.

TABLE X.—CALCULATED CONDUCTIVITY OF WATER IN EQUILIBRIUM WITH CO<sub>2</sub> OF AIR.

T.	Dilution of saturated soln.	Concentration of ionized solute.	$\Delta_{\infty}$ H <sub>2</sub> CO <sub>3</sub> .	Specific conductivity.
0°	34000 liters	$2.46 \times 10^{-6}$	264.0	$0.65 \times 10^{-6}$
18°	60000 liters	$2.13 \times 10^{-6}$	354.0	$0.75 \times 10^{-6}$
25°	71400 liters	$2.05 \times 10^{-6}$	393.4	$0.80 \times 10^{-6}$

It will be seen that, while the concentration of the ionized solute decreases slowly with rise of temperature, the ionic mobilities increase at a greater rate, hence the specific conductivity of the saturated solution, as shown in the last column of the table, *increases* with the temperature. The degree of accuracy of these values, taking into account the errors inherent in the standard value for the CO<sub>2</sub> content of the atmosphere, may be stated as  $\pm 5\%$ .

We may now proceed to the final step of the investigation—the comparison of the calculated values with those obtained by direct conductivity measurements. In the following table the figures for the specific conductivities of samples of carefully purified water in equilibrium with a normal laboratory atmosphere are collected. Measurements were carried out in each of the four laboratories already mentioned, at the three temperatures of 0°, 18° and 25°. The method of preparation of the conductivity water was the same in all cases—a single distillation from ordinary tap water to which a few cubic centimeters of Nessler's solution had been added.<sup>1</sup> The water so obtained was allowed to stand exposed to the ordinary laboratory atmosphere, and, after it had rapidly come to equilibrium with this, was found to give readings which were practically independent of the time. The conditions in each laboratory during the measurements were kept as nearly as possible the same as in the determination of the carbon dioxide content of the atmosphere. The conductivity work was carried out in small cells of the Arrhenius type in the usual manner.

<sup>1</sup> The preparation of conductivity water will be found fully described in the following paper.

TABLE XI.—MEASURED CONDUCTIVITY OF WATER IN EQUILIBRIUM WITH CO<sub>2</sub> OF AIR.

Laboratory.	Specific conductivity. (Reciprocal ohms $\times 10^{-4}$ .)		
	T. = 0°.	T. = 18°.	T. = 25°.
University of Edinburgh.....	.....	0.75-0.80	0.85-0.90
Technological Institute, Petrograd.....	0.60-0.70	0.80-0.85	0.85-0.90
Nobel Institute, near Stockholm.....	.....	.....	0.75-0.80
Columbia University, New York City....	0.60-0.65	0.70-0.80	0.75-0.85

The variations in the measured values are such as would be expected from the variations in the carbon dioxide content of the different laboratories.<sup>1</sup> The concordance of the values with those calculated is extremely satisfactory, as may be seen by comparison with the figures shown in the last column of Table X. The agreement obtained is, indeed, so striking as to warrant an emphatic repetition of the conclusion drawn by Walker and Cormack from their investigations,<sup>2</sup> that "*we may assume with confidence that carbon dioxide is the only substance in the atmosphere which confers conductivity on water.*"

Supplementary evidence in confirmation of the above assertion will be found in the succeeding paper, where the conductivity measurements of other observers on carefully purified water are collected and discussed. It will also be shown that solubility and electromotive force data support the assumption that *the purest distilled water of the laboratory is, in point of fact, a saturated solution of carbonic acid under the existing atmospheric conditions.* The significance of this in the interpretation of conductivity determinations at very high dilutions will then be examined in detail for electrolytes of different types.

### 9. Summary.

Exact values have been obtained, for temperatures of 0°, 18°, and 25°, for the following quantities necessary in the calculation of the specific conductivity of pure water in equilibrium with atmospheric carbon dioxide: (a) the ionization constant of carbonic acid; (b) the mobility of the hydrogen carbonate ion; (c) the carbon dioxide content of the atmosphere; (d) the solubility of carbon dioxide in water under atmospheric conditions.

The specific conductivity of a solution of carbonic acid at any given temperature is shown to be proportional to the square root of the partial pressure of carbon dioxide under which it exists.

The values for the specific conductivity of pure water in contact with air, derived with the use of the above data, are, for each temperature considered, practically identical with the directly-measured conductivity values.

The conclusion is drawn that carefully purified conductivity water really

<sup>1</sup> Compare Table VII.

<sup>2</sup> Walker and Cormack, *J. Chem. Soc.*, 77, 12 (1900).

consists of a saturated solution of carbonic acid under the partial pressure of the carbon dioxide in the atmosphere, and contains no other conducting impurities in appreciable quantity.

In a following paper some practical applications of this result in the correction of conductivity determinations at high dilutions will be developed, and further evidence of its validity will be brought forward.

### THE RARE EARTH COBALTICYANIDE.

BY C. JAMES AND P. S. WILLAND.

Received June 8, 1916.

The first rare earth cobalticyanide was prepared by Cleve and Hoeglund.<sup>1</sup> In 1915 the cobalticyanides were examined during a search for a method to separate yttrium from erbium,<sup>2</sup> and owing to the facts that the separation of yttrium from erbium was rapid, and that neodymium collected in the most soluble fractions, further investigations were carried out with the following results:

**Neodymium Cobalticyanide**,  $\text{Nd}_2(\text{CoC}_6\text{N}_6)_2 \cdot 9\text{H}_2\text{O}$ .—This compound was easily precipitated from a boiling solution of neodymium chloride by adding potassium cobalticyanide. Neodymium chloride was kept in excess. The salt, which possessed a pale lilac color, formed a heavy crystalline powder. Microscopic examination showed that the crystals belong to the hexagonal system. They were almost insoluble in water, very slightly soluble in concentrated hydrochloric acid, and rapidly decomposed by boiling sodium hydroxide.

In order to determine the percentage of neodymium, some of the material was boiled with sodium hydroxide to decompose it. The hydroxide, after filtering and washing well, was dissolved in dilute hydrochloric acid and precipitated as the oxalate. This was ignited and weighed. The average for the neodymium amounted to 32.80 per cent., which seemed to indicate that the formula should be  $\text{Nd}_2(\text{CoC}_6\text{N}_6)_2 \cdot 9\text{H}_2\text{O}$ . The cobalt was determined by electrolysis after breaking up the salt by fusion with bisulfate and rendering the solution alkaline by ammonium hydroxide. The results were a little below the theoretical.

When the compound was heated it gave off water and gradually turned blue. At higher temperatures it underwent rapid decomposition with the evolution of sparks.

**Yttrium Cobalticyanide**,  $\text{Y}_2(\text{CoC}_6\text{N}_6)_2 \cdot 9\text{H}_2\text{O}$ .—This salt was prepared by precipitating a boiling solution of yttrium nitrate with a hot solution of potassium cobalticyanide.

<sup>1</sup> *Bull. soc. chim.*, — 193-201 (1873).

<sup>2</sup> *THIS JOURNAL*, 37, 2642 (1915).

The precipitate was crystalline and creamy white in color. It was almost insoluble in water and hydrochloric acid, but was decomposed by boiling with sodium hydroxide.

The percentage of yttrium was determined in a similar manner to that of neodymium. The yttrium found amounted to 22.95%, indicating the presence of nine molecules of water of crystallization. From this it would seem that the rare earth cobaltcyanides possess the type formula  $R_2(\text{CoC}_6\text{N}_6)_2 \cdot 9\text{H}_2\text{O}$ .

Other cobaltcyanides were prepared in a similar manner to those described above. The lanthanum salt formed a heavy precipitate consisting of hexagonal bipyramids. They were a little more soluble in water than the neodymium compound, and were somewhat soluble in concentrated hydrochloric acid. Cerium cobaltcyanide was obtained as a white crystalline precipitate with a slightly yellow tint. The solubility in water and concentrated hydrochloric acid was of about the same degree as the lanthanum salt. Gadolinium cobaltcyanide formed very quickly. The precipitate was very finely divided and almost insoluble. Ytterbium cobaltcyanide was white, crystalline and insoluble. When a solution of potassium cobaltcyanide was boiled with a solution of thorium nitrate, no precipitate formed, even though the original volume had been greatly reduced.

In order to obtain some comparison of the solubilities of these compounds, they were rotated in a thermostat with 10% hydrochloric acid. Three grams of each salt were placed in a bottle with 50 cc. of hydrochloric

acid having a sp. gr. of 1.050 at 15°. After they had rotated for two weeks at 25°, they were allowed to settle. Some of the liquid was weighed, precipitated with oxalic acid and allowed to stand fifteen hours before filtering, igniting and weighing. From these results the parts per thousand were calculated and plotted against the atomic weights.

Compound.	Atomic weight.	Parts per thousand.
$\text{La}_2(\text{CoC}_6\text{N}_6)_2 \cdot 9\text{H}_2\text{O}$ .....	139.0	10.41
$\text{Ce}_2(\text{CoC}_6\text{N}_6)_2 \cdot 9\text{H}_2\text{O}$ .....	140.25	10.75
$\text{Nd}_2(\text{CoC}_6\text{N}_6)_2 \cdot 9\text{H}_2\text{O}$ .....	144.3	4.19
$\text{Gd}_2(\text{CoC}_6\text{N}_6)_2 \cdot 9\text{H}_2\text{O}$ .....	157.3	1.86
$\text{Yb}_2(\text{CoC}_6\text{N}_6)_2 \cdot 9\text{H}_2\text{O}$ .....	172.0	0.38
$\text{Y}_2(\text{CoC}_6\text{N}_6)_2 \cdot 9\text{H}_2\text{O}$ .....	89.0	2.78

The curve obtained from the above data shows that yttrium cobalticyanide is of about the same solubility as the samarium and europium compounds, and more than three times more soluble than the erbium salt. The separation of yttrium and terbium would seem to be less efficient, since the terbium salt is about twice as soluble as that of erbium.

#### Separation of Mixed Oxides.

1. Oxides containing dysprosium, holmium, and yttrium, with traces of erbium, terbium and neodymium. These were dissolved in nitric acid, diluted to about 600 cc., boiled, and a solution of potassium cobalticyanide added until a quantity of precipitate had formed. This was filtered off and the process repeated. The precipitates were boiled with sodium hydroxide, filtered, washed and dissolved in nitric acid. The solutions were then precipitated as the oxalates, ignited and again converted into the nitrates, the solutions of which were examined by means of a spectroscope.

Fraction I showed very strong holmium and dysprosium bands and traces of neodymium and erbium. In Fraction II holmium and dysprosium were still very strong, neodymium was weak and there was a trace of erbium. Fraction III showed strong neodymium dysprosium and holmium bands. There was a slight trace of erbium. In Fraction IV, neodymium was stronger while holmium and dysprosium were weak. The material was mainly yttrium nitrate.

Fraction I was diluted, boiled and more cobalticyanide added. The precipitate that formed was filtered off and the remaining rare earth thrown out as the oxalate. These

Fractions, V and VI, were converted to the oxides. V was again dissolved in nitric acid and split into two more fractions as shown in the sketch herewith.

In color the oxides varied from a chocolate-brown to a light chamois proportional to the equivalents, showing that terbium tends to go to the least soluble end. All the oxides were boiled with water to remove any alkali metal before the equivalents were determined.

No. of fraction.	II.	III.	IV.	VI.	VII.	VIII.
Atomic weight.....	109.5	95.2	89.0	102.3	132.9	122.4

2. Separation of erbium from yttrium. The oxide used was very rich in erbium. Twenty-five grams were dissolved in hydrochloric acid, diluted to about 800 cc. and precipitated as in the case of the dysprosium, holmium and yttrium oxides. Two fractions were taken, and these, after converting to oxides and redissolving, were again fractioned. Fraction I gave Fractions III, IV and V, while Fraction II gave Fractions VI and VII. The oxides varied from a rose color to an extremely pale pink. Fraction III, the least soluble, possessed the most color, and Fraction VII, the most soluble, was the palest.

No. of fraction.	III.	IV.	V.	VI.	VII.
Atomic weight.....	142.3	137.2	127.8	110.1	93.7

The cobaltcyanide method is excellent for the separation of yttrium from erbium and *vice versa*. The precipitates are very crystalline, and the process can be quickly carried out.

One of the authors and another are investigating the ferricyanides, which are nice crystalline compounds and which differ very considerably in their solubilities. By fractionally precipitating a solution of the nitrates of yttrium and erbium with potassium ferricyanide, a rapid separation is effected.

## AMMONIUM IODIDE, ITS SOLUBILITIES AND THE ABSENCE OF A TRANSITION POINT.

BY ALEXANDER SMITH AND HERBERT E. EASTLACK.

Received June 12, 1916.

Wallace<sup>1</sup> observed no irregularities in the cooling curves of ammonium iodide between 220° and -16.5°, and no change under the microscope between 16° and the sublimation point. He notes that, while the chloride and bromide crystallize in pentagonal icositetrahedra, there is some evidence that above their transition point they are cubical, just like the iodide, and the alkali iodides. He refers also to Tuton's<sup>2</sup> statement that the molecular volumes of ammonium sulfate and its double salts lie between those of rubidium and caesium, and himself found that, of the am-

<sup>1</sup> *Centr. Min.*, 1900, 33.

<sup>2</sup> *Z. Kryst.*, 38, 602 (1904); 41, 321 (1906).

monium halides, only the iodide showed this relation. Wallace concluded, therefore, that the transition point of the iodide, if there is any, must lie below  $-16.5^{\circ}$ , and that the ordinary form of the salt is the one stable above this point.

Although the transition points of the chloride and bromide are high, the transformations on cooling are sluggish. It seemed possible, therefore, that the iodide might possess a transition point below the temperature at which it is ordinarily crystallized from solution, and that, on account of the low temperature of transition, the point might have escaped notice. Definite information being necessary for other work being done in this laboratory, heating and cooling curves were made, without result. The solubility curve of ammonium iodide in water was then determined from  $-19^{\circ}$  to  $136^{\circ}$ . Except for one measurement by Eder<sup>1</sup> at  $15^{\circ}$ , and three analyses of the cryohydrate at  $-27.5^{\circ}$  by Guthrie,<sup>2</sup> the literature contains no solubility measurements with this salt. The continuity of our solubility curve shows conclusively that, at one atmosphere pressure, no transition point exists between the above-mentioned temperatures. Considering that the transition point of the chloride is higher than that of the bromide, and the comparative ease with which a transition point, if it existed, could have been observed at higher temperatures, the solubility curve of the iodide was not carried above the transition point of the bromide.

**Solubility Measurements.**—The ammonium iodide was recrystallized twice from distilled water, was washed with alcohol and ether, and was heated for ten hours at  $115^{\circ}$  in an air bath to expel volatile impurities. It was perfectly white. The method employed was identical with that used by us with ammonium bromide.<sup>3</sup> For the points below  $0^{\circ}$ , an alcohol bath, cooled by a freezing mixture, was employed. By immersing the sealed bulb containing the ammonium iodide and water, for a few seconds, in a mixture of solid carbon dioxide and ether, the minute crystals, required for determining the equilibrium points when approached from below, were obtained. Although more time was needed for reaching equilibrium at the low temperatures, the saturation temperatures could be determined  $\pm 0.5^{\circ}$ . In the tables, the solubilities are in grams of  $\text{NH}_4\text{I}$  per 100 g. water.

Eder's determination at  $15^{\circ}$  (167 g.) lies very close to our curve. Guthrie's analyses of the cryohydrate at  $-27.5^{\circ}$  are so erratic that two of his determinations fall above, while the third falls below the extension of our curve.

**Summary.**—The solubilities of ammonium iodide have been measured between —19° and 136°.

The points lie on a single smooth curve, thus confirming Wallace's conclusion regarding the non-existence of a transition point within the same range of temperatures.

### NOTE.

**A Non-Spattering Wash Bottle.**—To avoid spattering at the tip of the nozzle of the ordinary wash bottle the principle of raising the water-table of the wash bottle slightly above the level of the tip of the nozzle has been adopted so that "back action" will not take place and the nozzle tube will remain permanently full of water.

A careful study of the diagram will make the principle clear. While in use the thumb is held over the pressure release D, the water is forced up through the tube C till the water-table indicated, has been reached, the water level being maintained by the stopper F. The nozzle works the same as though the wash bottle were full up to the raised water level. Before releasing the pressure from the mouth piece the thumb is taken off the tube D so that the height of the water-table in A may be insured and to prevent "back action" through B.

In construction the following details are important:

1. Make D 5 mm. or as large as possible to afford a quick release of pressure, having it project only to the bottom of the small cork in A.
2. The size (4 mm.) and length of B are not important just so the bottom projects an inch or so below the water-table.
3. The stopper F should be near the bottom of A for best results.

4. The tube A (12 mm.) projects up through the stopper and to the bottom of the bottle.

5. The intake C should be 4 mm. or as small as possible and still give sufficient flow. Its height determines the height of the water-table.

**Note.**—All calibrations are outside measurements. F. C. CLAPP.

**RELATIONS BETWEEN THE CONSTANTS OF DIBASIC ACIDS  
AND OF AMPHOTERIC ELECTROLYTES.**

BY ELLIOT QUINCY ADAMS.

Received April 4, 1916.

This paper comprises some remarks on the ionization of polybasic acids, of their acid esters, of polyacid bases, and of amphoteric electrolytes.

The fact that the two dissociation constants of a dibasic acid seldom differ by a factor *less* than four or five appears in all experimental studies of such constants,<sup>1</sup> and Walker<sup>2</sup> observed that the constants of acid esters of symmetrical dibasic acids are never<sup>3</sup> more than half those of the acids from which they are derived. In the following discussion it will be shown that these results are to be expected.

The term amphoteric is applied to two classes of compounds—hydroxyl compounds, like  $\text{Zn}(\text{OH})_2$ , which may lose either hydroxyl or hydrogen ion—and compounds like the amino acids which may gain or lose hydrogen ion; and in the latter case the practice of expressing the “base constant” of such electrolytes in terms of hydroxide ion concentration has very greatly obscured the results.<sup>4</sup>

In this paper the constants for amino acids and amines will be expressed in terms of hydrogen ion concentration, *e. g.*, for aniline<sup>5</sup>  $K = (\text{C}_6\text{H}_5\text{NH}_2) \cdot (\text{H}^+) / (\text{C}_6\text{H}_5\text{NH}_3^+)$ .

The first point to be investigated will be the relation between the two ionization constants of a dibasic acid. The ionization of such an acid is represented in Fig. 1 in which the two ionizable hydrogens are distinguished by being written, respectively, before and after the symbol A of the negative radical.  $K_1$ ,  $K_2$ ,  $K_3$ ,  $K_4$  are the respective constants for the reactions  $\text{HAH} \rightleftharpoons \text{H}^+ + \text{AH}^-$ ,  $\text{HAH} \rightleftharpoons \text{HA}^- + \text{H}^+$ ,  $\text{HA}^- \rightleftharpoons \text{H}^+ + \text{A}^{--}$ ,  $\text{AH}^- \rightleftharpoons \text{A}^{--} + \text{H}^+$ , namely,  $K_1 = (\text{H}^+)(\text{AH}^-)/(\text{HAH})$ , etc.

Fig. 1.

(It follows that  $K_1K_4 \equiv K_2K_3$ .)

Expressions for the first and second ionization constants as ordinarily defined,  $K'$  and  $K''$ —since  $(\text{AH}^-) + (\text{HA}^-)$  is the total concentration of intermediate ion—may be derived as follows:

$$K' = \frac{[(\text{AH}^-) + (\text{HA}^-)](\text{H}^+)}{(\text{HAH})} = K_1 + K_2 \quad (1)$$

$$K'' = \frac{(\text{A}^{--})(\text{H}^+)}{(\text{AH}^-) + (\text{HA}^-)} = \frac{1}{1/K_4 + 1/K_3} = \frac{K_3K_4}{K_3 + K_4} \quad (2)$$

From these general equations may be derived the simpler equations for certain special cases.

<sup>1</sup> Cf. E. E. Chandler, *THIS JOURNAL*, 30, 707 (1908).

<sup>2</sup> J. Walker, *J. Chem. Soc.*, 61, 715-7 (1892).

<sup>3</sup> Adipic acid (*Loc. cit.*) is only an apparent exception, for the fall in the observed constant on dilution shows clearly, as Walker himself pointed out, the presence of some conducting impurity.

<sup>4</sup> As will be shown later.

<sup>5</sup> In the following equation  $(\text{C}_6\text{H}_5\text{NH}_2)$  means the aggregate concentration of aniline and all of its hydrates, just as  $(\text{H}^+)$  means the aggregate concentration of hydrogen ion and all of its hydrates, etc.

The simplest of these is that in which the acid is symmetrical and the hydrogens independent of each other's ionization. Then  $K_1 = K_2 = K_3 = K_4 = K$  and Equations 1 and 2 become

$$K' = 2K; K'' = \frac{1}{2}K. \quad (3) (4)$$

The condition of symmetry is easily satisfied, that of adequate separation of the hydrogens not so easily, for in the "straight chain" of five or six carbon atoms ring formation is possible and hence the ends of the chain may be near one another even when no ring is formed. In the derivatives of triphenylmethane the rigidity of the benzene rings may be trusted to keep *para*-substituents in the several rings apart; and the best examples of Equations 3, 4 are found in such derivatives. Thus the two constants for phenolphthalein<sup>1</sup> as determined colorimetrically by Rosenstein<sup>2</sup> are  $K' = 11.5 \times 10^{-10}$ ,  $K'' = 2.83 \times 10^{-10}$ , whence  $K'/K'' = 4.06$ , while the first two constants of crystal violet as determined spectrophotometrically by Adams and Rosenstein<sup>3</sup> and expressed in terms of acid concentration (although crystal violet is a base) are  $1.62 \times 10^{-2}$  and  $6.6 \times 10^{-2}$ , whence  $K'/K''$  for the yellow salt, regarded as a dibasic acid, is 4.08. The extreme closeness to 4 is accidental, as the ratio, in the second case at least, is uncertain to five per cent. or more.

Chandler<sup>4</sup> has shown that the ratio of the constants for dibasic organic acids approaches this value at high concentrations.

For *independently* ionizable hydrogens in an unsymmetrical acid  $K_3 = K_1$ ,  $K_4 = K_2$  and Equation 2 becomes

$$K'' = \frac{K_1 K_2}{K_1 + K_2}. \quad (5)$$

If the hydrogens are not sufficiently separated to ionize independently, we may generalize from the behavior of oxalic acid and its immediate homologs, whose first constants are markedly greater and whose second constants are distinctly less than the ionization constants of the corresponding fatty acids; and state the principle that a negative group in-

<sup>1</sup> Un-ionized phenolphthalein and its singly charged ion are colorless, and are therefore supposed to be entirely in the lactone form; the doubly charged ion is pink and consists of a mixture, in tautomeric equilibrium, of the ion of colorless phenolphthalein and that of an unsymmetrical quinoid phenol-acid,  $O:C_6H_4:C(C_6H_4OH)-C_6H_4CO_2H$ . Since the ratio of the two constants, determined experimentally, agrees with that for a symmetrical dibasic acid, the quinoid ion can constitute only a few per cent., at most, of the tautomeric mixture.

<sup>2</sup> I. Rosenstein, *THIS JOURNAL*, **34**, 1117 (1912); cf. phenol,  $K = 1.1 \times 10^{-10}$ .

<sup>3</sup> E. Q. Adams and I. Rosenstein, *THIS JOURNAL*, **36**, 1452 (1914). In crystal violet the quinoid basic group is not involved in the change from the violet to the green and yellow forms. The two remaining nitrogens are equivalent, hence the yellow ion is symmetrical with respect to the two hydrogens which it is able to lose.

<sup>4</sup> E. E. Chandler, *THIS JOURNAL*, **30**, 707 (1908).

creases and a negative charge diminishes the ionizability of any hydrogen in the molecule, whence  $K_3 < K_1$ ,  $K_4 < K_2$  and Equation 2 becomes

$$K'' < \frac{K_1 K_2}{K_1 + K_2} \quad (6)$$

Dividing (1) by (6)

$$\frac{K'}{K''} > \frac{(K_1 + K_2)^2}{K_1 K_2} > \frac{(K_1 + K_2)^2}{K_1 K_2} - \frac{(K_1 - K_2)^2}{K_1 K_2}$$

but

$$\frac{(K_1 + K_2)^2}{K_1 K_2} - \frac{(K_1 - K_2)^2}{K_1 K_2} = \frac{4K_1 K_2}{K_1 K_2} = 4,$$

whence

$$\frac{K'}{K''} > 4. \quad (7)$$

That is to say, the first ionization constant will in general be more than four times<sup>1</sup> the second, the limiting ratio of 4 being found in *symmetrical* acids whose hydrogens are widely separated (and, therefore, *independently ionizable*).

For a *tribasic* acid it may be shown in similar fashion that the limiting ratio between successive constants is 3; indeed the calculation may be made for an acid with any number of hydrogens.

The truth of the conclusion for dibasic acids may be seen in Table I. The data are taken, unless otherwise indicated from Scudder,<sup>2</sup> and are, in general, at 25°.

The acid esters of dibasic acids will differ from the acids in two ways: by the loss of one hydrogen and by the effect on the other hydrogen of the substitution. If the second effect—which will be in general a decrease in the “polar character” of the molecule and, therefore, of the ionization—be neglected, then, as Wegscheider<sup>3</sup> showed, the ionization constant for the *acid ester* of a *symmetrical* dibasic acid will be one-half the first constant of the acid, and the *sum* of the constants for the two isomeric acid esters of an *unsymmetrical* dibasic acid will be *equal* to the first constant of the acid. Table II shows in how far this expectation is borne out.

To amphoteric electrolytes Equations 1, 6 and 7 derived above, apply directly if the constant of the basic part of the molecule be expressed in terms of hydrogen ion concentration. Much of the supposedly anomalous behavior of amphoteric electrolytes is due to the neglect of the possibility that the constants so expressed will be related in such a

way that the constant determined in acid solution is the acid constant and that in alkaline solution the basic constant.

Aminoacetic acid, for example, has the constants  $K_A = 1.8 \times 10^{-10}$ ,  $K_B = 2.8 \times 10^{-12}$ , which become in the notation used in this article  $K'' = 1.8 \times 10^{-10}$ ,  $K' = \frac{1.0 \times 10^{-14}}{K_B} = 3.7 \times 10^{-3}$ , which are to be

compared with the constants for methylamine  $K = \frac{1.0 \times 10^{-14}}{4.1 \times 10^{-14}} = 2.4 \times 10^{-11}$ , N-benzoyl aminoacetic acid,  $K = 2.2 \times 10^{-4}$ , acetic acid,  $K = 1.8 \times 10^{-5}$ , N-acetyl aminoacetic acid,  $K = 2.3 \times 10^{-4}$ , chloroacetic acid,  $K = 1.6 \times 10^{-3}$ , showing that aminoacetic acid is at once an acid stronger than monochloroacetic acid and a base nearly as strong as methylamine.

<sup>1</sup> By inversion; by partition =  $4.4 \times 10^{-6}$ .

<sup>2</sup> By inversion; by conductivity =  $1.9 \times 10^{-6}$ ; by partition =  $3.7 \times 10^{-6}$ .

<sup>3</sup> By conductivity; by partition =  $3.3 \times 10^{-6}$ .

<sup>4</sup> By conductivity; by partition  $2.0 \times 10^{-7}$ ; by inversion  $3.9 \times 10^{-7}$ ,  $5.5 \times 10^{-7}$ .

<sup>5</sup> By partition and inversion; by conductivity  $3.0 \times 10^{-6}$ .

<sup>6</sup> By partition; by conductivity  $3.9 \times 10^{-6}$ ; by inversion  $1.7 \times 10^{-6}$ ,  $2.2 \times 10^{-6}$ .

<sup>7</sup> By conductivity; by partition  $2.7 \times 10^{-6}$ ; by inversion  $1.0 \times 10^{-6}$ .

<sup>8</sup> These values are given for *d*-, *l*-, and *dl*-camphoric acids. Chandler (*Loc. cit.*) gives for the second constant of *d*-camphoric acid (by conductivity)  $K'' = 14 \times 10^{-8}$ , but he uses  $K' = 2.3 \times 10^{-4}$  in his calculations (apparently by mistake). As camphoric acid is an unsymmetrical acid it was rather surprising to find for it constants whose ratio is less than 2.

<sup>9</sup> Landolt-Börnstein Tabellen (1912 edition).

		Propyl	$0.15 \times 10^{-3}$	$0.93 \times 10^{-3}$

Since K' is several million times as great as K", and is unquestionably the measure of the ionization of the carboxyl, aminoacetic acid will be almost exclusively the "inner salt,"  $\text{N}^+\text{H}_3\text{CH}_2\text{CO}_2^-$ , with less than one part per million of true amino acid,  $\text{NH}_2\text{CH}_2\text{CO}_2\text{H}$ . In the case of the aminobenzoic acids (see below) this fraction becomes about 1%. It should be pointed out that aminoacetic acid appears to be an exception to the general rule that a negative charge diminishes the ionization of any hydrogen in the molecule, for whereas acetic acid,  $\text{CO}_2\text{HCH}_3$ , loses its hydrogen more readily than acid malonate ion,  $\text{CO}_2\text{HCH}_2\text{CO}_2^-$ , methylammonium ion,  $\text{N}^+\text{H}_3\text{CH}_3$ , loses hydrogen ion less readily than aminoacetic acid,  $\text{H}^+\text{N}_3\text{CH}_2\text{CO}_2^-$ . The aminobenzoic acids do not show this anomaly, for, as bases, they are stronger than aniline.

<sup>1</sup> The data are from Scudder, but the designations  $\alpha$  and  $\beta$  have been interchanged in the case of the methyl and propyl esters to agree with Wegscheider, as Scudder quotes Wegscheider and assigns no reason for the changes.

Comparing the aminobenzoic acids with benzoic acid,  $K = 6.7 \times 10^{-5}$  and aniline  $K = 1.0 \times 10^{-14}/4.6 \times 10^{-10} = 2.2 \times 10^{-5}$ , and with their respective N-acetyl derivatives:

Acid.	$K_B = 1.0 \times 10^{-14}/K'$	$K'$	$K_A = K''$	$K(\text{acetyl-})$
<i>o</i> -Aminobenzoic.....	$1.37 \times 10^{-12}$	$7.3 \times 10^{-3}$	$1.1 \times 10^{-5}$	$2.4 \times 10^{-4}$
<i>m</i> -Aminobenzoic.....	$1.22 \times 10^{-11}$	$0.82 \times 10^{-3}$	$1.6 \times 10^{-5}$	$0.85 \times 10^{-4}$
<i>p</i> -Aminobenzoic.....	$2.33 \times 10^{-12}$	$4.3 \times 10^{-3}$	$1.2 \times 10^{-5}$	$0.52 \times 10^{-4}$
Chloroacetic acid.....	.....	$1.6 \times 10^{-3}$	.....	.....
<i>m</i> -Toluidine.....	$5.8 \times 10^{-10}$	.....	$1.7 \times 10^{-5}$	.....
<i>p</i> -Toluidine.....	$1.8 \times 10^{-10}$	.....	$0.56 \times 10^{-5}$	.....

the meta-acid is thus slightly weaker than monochloroacetic acid, the ortho- and para-acids stronger, while as bases all three lie between *m*- and *p*-toluidine, the ortho-acid being twice as strong a base as aniline.

The strongly *negative* character of the  $\text{NH}_2$  group may also be seen in the antagonistic action of neighboring  $\text{NH}_2$  groups.

	$K_B = K_w/K$	$K'$		$K_1 = K_w/K''$	$K''$

### Summary.

1. For polybasic acids the ionization constants  $K'$  and  $K''$  as ordinarily defined are related to the constants,  $K_1$ ,  $K_2$ , for the separate removal of the respective hydrogens, thus:

$$K' = K_1 + K_2 \quad (1)$$

$$K'' < \frac{K_1 K_2}{K_1 + K_2}, \quad (6)$$

whence

$$\frac{K'}{K''} > 4. \quad (7)$$

2. Phenolphthalein and crystal violet give values for this ratio very near the limiting value. (At high concentrations of dibasic organic acids, E. E. Chandler has shown that this same limit is approached.)

3. The acid esters of a symmetrical dibasic acid have constants equal to approximately one-half the first constant of the acid, while the sum of the constants of the isomeric esters of an unsymmetrical dibasic acid is approximately equal to the first constant of the acid. (This generalization is due to Wegscheider.)

<sup>1</sup> Not given in Scudder.

<sup>2</sup> Normal amine not given.

<sup>3</sup> For ethylenediamine  $K' = 1.0 \times 10^{-14}/6.0 \times 10^{-7} = 1.7 \times 10^{-8}$ ; for the others it is not given. It is to be remembered that a larger constant means a stronger acid or a weaker base.

4. The constants of aminoacetic acid and the aminobenzoic acids are explained by the strong *negative* character of the  $\text{NH}_2$  group.

[CONTRIBUTION FROM THE DEPARTMENT OF CHEMISTRY OF THE UNIVERSITY OF KANSAS.]  
ON THE REACTIONS OF THE FORMAMIDINES. V. ON SOME  
PYRAZOLONE DERIVATIVES.

By F. B. DAINS, H. R. O'BRIEN AND C. L. JOHNSON.

Received May 31, 1916.

This is a continuation of a previous investigation on the pyrazolones,<sup>1</sup> where it was shown that the methylene group in this class of derivatives reacted with the formamidines, the hydrogen being replaced by the group  $>\text{CHNHR}$ . The general equation can be formulated as follows,

the reaction yielding a substituted 4-amino methylene pyrazolone and the free amine. The following paper includes further experimental evidence as to the general nature of this reaction and a partial study of the action of certain reagents upon the substituted pyrazolones.

**4-*m*-Toluido-methylene-1-*p*-tolyl-3-methyl-5-pyrazolone,**

Molar quantities of the pyrazolone and di-*m*-tolyl formamidine were heated for twenty minutes in an oil bath at 150°. From the reaction product the new compound was isolated after treatment with dilute hydrochloric acid, which removed *m*-toluidine. This separated from alcohol in golden yellow crystals melting at 122°.

Calc. for  $C_{19}H_{19}ON_3$ : N, 13.78%. Found, 13.85%.

Under like conditions the pyrazolone and di-*o*-tolyl formamidine gave 4-*o*-toluido-methylene-1-*p*-tolyl-3-methyl-5-pyrazolone, yellow needles from alcohol which melt at 176.5°.

Calc. for  $C_{19}H_{19}ON_3$ : N, 13.78%. Found: 13.86%, 13.69%.

The ease of reaction of different formamidines seems to vary greatly. While many require heating at 120–150° in order to ensure condensation, others unite at much lower temperature. Thus *p*-tolyl methyl pyrazolone and di-*o*-phenetidyl formamidine at water-bath temperature gave the amine and 1-*p*-tolyl-3-methyl-4-*o*-ethoxyanilido-5-pyrazolone. It crystallizes from alcohol in canary-yellow needles with a melting point of 133°. The same reaction occurs slowly when the components are ground together in a mortar and allowed to stand.

<sup>1</sup> Dains and Brown, *THIS JOURNAL*, 31, 1153 (1909).

Calc. for  $C_{20}H_{21}O_2N_2$ : N, 12.54%. Found: 12.80%.

In some cases a secondary reaction was found to occur, which resulted in the formation of varying amounts of a bispyrazolone.

Thus the above pyrazolone and di-*p*-bromo-diphenyl formamidine gave on heating 1-*p*-tolyl-3-methyl-4-*p*-bromo-anilido-methylene-5-pyrazolone, yellow crystals from alcohol with a melting point of 196–7°.

Calc. for  $C_{18}H_{16}O_3MgBr$ : Br, 21.60%. Found: 21.29%.

In addition there is formed a bromine-free compound, difficultly soluble in alcohol, which crystallizes from chloroform in orange needles, melting at 249°. It gave on analysis the figures demanded for methenyl-bis-methyl-*p*-tolyl-pyrazolone.

Calc. for  $C_{22}H_{22}O_2N_4$ : N, 14.51%. Found: 14.77%, 14.78%.

This constitution was confirmed by the fact that the same methenyl bispyrazolone was obtained, together with *m*-toluidine, when di-*m*-tolyl formamidine (one mol) was heated with the methyl *p*-tolyl pyrazolone (two mols).

Analogous results were obtained in one experiment when a mixture of *o*-tolyl-3-methyl-5-pyrazolone and di-*p*-chloro-diphenyl formamidine was heated. Besides *p*-chloro-aniline, the only product isolated was methenyl-bis-1-*o*-tolyl-3-methyl-5-pyrazolone, which crystallizes from alcohol in orange-colored needles, melting at 190°.

Calc. for  $C_{22}H_{22}O_2N_4$ : N, 14.51%. Found: 14.75%.

The same product is obtained when the methyl-tolyl-pyrazolone is heated with orthoformic ester at 120°, thus showing the analogy in behavior of this class of compounds with both orthoformic ester and the formamidines.<sup>1</sup>

Another method of obtaining these derivatives is to heat an anilido-methylene-pyrazolone with an unsubstituted pyrazolone. Thus anilido-methylene-methyl-phenyl-pyrazolone and the methyl-phenyl-pyrazolone yield aniline and the bispyrazolone.

**1-*o*-Tolyl-3-methyl-5-pyrazolone and the Formamidines.**—Instead of simply fusing the components alone in an oil bath, in the following cases, it was found that better and cleaner yields of the amino-methylene derivatives were obtained when the substances were heated in a high boiling solvent such as xylene or kerosene. In this way the following were synthesized:

<sup>1</sup> THIS JOURNAL, 31, 1153 (1909).

1-*o*-Tolyl-3-methyl-4-anilido-methylene-5-pyrazolone, reddish brown crystals from alcohol, which melt at 140°.

Calc. for  $C_{18}H_{17}ON_3$ : N, 14.43%. Found: 14.14%, 14.43%.

1-*o*-Tolyl-3-methyl-4-*m*-xylylido-5-pyrazolone, yellow needles, melting point, 232°.

Calc. for  $C_{20}H_{21}ON_3$ : N, 13.09%. Found: 13.29%, 13.19%.

1-*o*-Tolyl-3-methyl-4-*o*-ethoxyanilido-methylene-5-pyrazolone, yellow crystals from alcohol which melt at 160°.

Calc. for  $C_{20}H_{21}O_2N_3$ : N, 12.53%. Found: 12.64%.

1-*o*-Tolyl-3-phenyl-5-pyrazolone, which was made from *o*-tolyl hydrazine and benzoyl-acetic ethyl ester, was found to react with the same ease with the substituted formamides, a fact illustrated by the following preparations.

1-*o*-Tolyl-3-phenyl-4-anilido-methylene-5-pyrazolone, from the pyrazolone and di-phenyl formamidine in boiling xylene solution, crystallizes from alcohol in light yellow needles, which melt at 169°.

Calc. for  $C_{22}H_{19}ON_3$ : N, 11.90%. Found: 11.92%, 11.87%.

The same pyrazolone and di-*m*-xylyl formamidine gave 1-*o*-tolyl-3-phenyl-4-*m*-xylylido-methylene-5-pyrazolone, yellow crystals also from alcohol, melting point 142°.

Calc. for  $C_{22}H_{23}ON_3$ : N, 11.02%. Found: 11.16%, 11.40%.

1-*o*-Tolyl-3-phenyl-4-*p*-chloroanilido-methylene-5-pyrazolone, yellow crystals which melt at 181°.

Calc. for  $C_{23}H_{17}ON_3Cl$ : N, 11.34%. Found: 11.05%, 11.12%.

Derivatives of 1-phenyl-3-methyl-5-pyrazolone. This reacts at water-bath temperature with di-*o*-ethoxyphenyl formamidine, yielding 1-phenyl-3-methyl-4-*o*-ethoxyanilido-methylene-5-pyrazolone, yellow needles which melt at 170°.

Calc. for  $C_{19}H_{19}O_2N_3$ : N, 13.09%. Found: 13.23%.

1-Phenyl-3-methyl-4-*m*-xylylidomethylene-5-pyrazolone, golden yellow needles difficultly soluble in alcohol, melting at 173°.

Calc. for  $C_{19}H_{19}ON_3$ : N, 13.65%. Found: 13.63%, 13.77%.

It has been shown that not only do compounds with a methylene group-  
ing react with the formamides, but also that their aldehyde condensa-  
tion products in some cases behave in a similar manner. Thus 4-benzal-  
3-methyl-isoxazolone unites with the formamides yielding benzal aniline  
and the amino-methylene derivatives much more readily and smoothly  
than does the free methyl isoxazolone.<sup>1</sup>

This same fact holds true in the case of the aldehyde condensation  
products of the pyrazolones. When 4-benzal or anisal-1-phenyl-3-  
methyl-5-pyrazolone is heated with diphenyl formamidine,<sup>2</sup> there is ob-

<sup>1</sup> Dains and Griffin, *THIS JOURNAL*, 35, 962 (1913).

<sup>2</sup> *Ibid.*, 31, 1153 (1909).

tained benzal aniline and 4-anilido-methylene-methyl-phenyl-pyrazolone, m. p. 154°.

Tambor<sup>1</sup> obtained from piperonal and methyl-phenyl-pyrazolone (equal mols), the red piperonal-methyl-phenyl-pyrazolone (m. p. 166–7°), while piperonal (one mol) and the pyrazolone (two mols) gave piperonal-di-(methyl-phenyl-pyrazolone), a white compound melting at 143°. Repeating this work it was found that the white piperonal-dipyrazolone has the higher melting point of 163°. This was heated with diphenyl formamidine with the hope of replacing the  $C_6H_5N$  < rest with two pyrazolone groups. This aim was not realized, the reaction product yielding aniline, anilido-methylene-methyl-phenyl-pyrazolone (m. p. 154°) and the red piperonal pyrazolone. The white piperonal-dipyrazolone evidently dissociates into the simple pyrazolone and the red aldehyde condensation product.

**The Action of the Amino-methylene-pyrazolones with Various Reagents. Hydrochloric Acid.**—The amino-methylene derivatives are capable of forming hydrogen chloride addition products, stable in benzene, though decomposed by water. Thus dry HCl gas precipitates from a benzene solution of 1-phenyl-3-methyl-4-*m*-xylidomethylene-5-pyrazolone a white hydrochloride melting at 189–90°.

Calc. for  $C_{19}H_{19}ON_2HCl$ : HCl, 10.67%. Found: 10.73%.

In like manner, dry hydrogen chloride gas, when passed into a benzene solution of anilido-methylene-methyl-phenyl-pyrazolone, gave a white HCl addition product, melting and decomposing at 186°.

However, if the anilido compound is boiled in an alcoholic solution of hydrochloric acid, decomposition ensues with the formation of aniline and varying but small amounts of methenyl-bismethyl-phenyl-pyrazolone (m. p. 180°).

Similar results were obtained on hydrolysis with potassium hydroxide. For instance, 4-anilido-methylene-1-*o*-tolyl-3-phenyl-5-pyrazolone was heated for a few minutes with alcoholic potash. On examination the reaction mixture was found to contain aniline and a product which separated from gasoline in orange-yellow crystals, melting at 179°. This was identified as methenyl-4-4-bis-1-*o*-tolyl-3-phenyl-5-pyrazolone, which was also readily prepared by heating the pyrazolone (two mols) with ortho-formic ester (one mol) at 120°. It is difficultly soluble in alcohol.

Calc. for  $C_{33}H_{28}O_2N_4$ : N, 10.98%. Found: 11.00%, 11.20%.

**The Action of Nitric Acid.**—To a cooled solution of anilido-methylene-methyl-phenyl-pyrazolone in concentrated sulfuric acid, was added nitric

<sup>1</sup> Ber., 33, 869 (1900).

acid (one mol sp. gr. 1.42). The product obtained by pouring the mixture into cold water was practically insoluble in alcohol, chloroform or gasoline. It was purified by recrystallization from pyridine. From this solvent it separates in brownish yellow needles, which char between 255–265°. It is unaffected by boiling hydrochloric acid under ordinary conditions, but at 150° in a sealed tube some *p*-nitro-aniline was obtained. Analysis gave discordant figures, indicating that it was a mixture of nitro products in which both the phenyl group of the ring and the side chain were nitrated.

For comparison two derivatives were prepared with a nitro group in the side chain. Phenyl-methyl-pyrazolone condenses with di-*m*-nitro-diphenyl-formamidine in boiling kerosene solution yielding 1-phenyl-3-methyl-4-*m*-nitro-anilido-methylene-5-pyrazolone, yellow needles from alcohol melting at 175°.

Calc. for  $C_{17}H_{14}O_3N_4$ : N, 17.40%. Found: 17.23%.

The corresponding 1-phenyl-3-methyl-4-*p*-nitro-anilido-methylene-5-pyrazolone separates from alcohol in orange-yellow needles which melt at 170°.

Calc. for  $C_{17}H_{14}O_3N_4$ : N, 17.40%. Found: 17.63%.

**The Action of Bromine.**—The synthesis of the amino-methylene compounds by the action of aniline on ethoxy-methylene-aceto acetic ester and of the formamidines on the benzal derivatives of the isoxazolones and pyrazolones shows that they possess the constitution  $>C = CHNHR$ . At the same time, the mechanism of the reaction by which there is formed from them pyrazol and isoxazol compounds and their behavior with bromine prove that they also exist and react in the tautomeric form<sup>1</sup>  $>CHCH = NR$ . This latter form is capable of adding two atoms of bromine and this addition product under the influence of solvents may either lose its bromine entirely or may undergo rearrangement yielding a mono-bromo substitution product and hydrogen bromide. Thus the bromine derivatives of anilido-methylene-methyl-isoxazolone and of anilido-methylene-cyanacetic ester rearrange to the corresponding *p*-bromo-anilido compounds.<sup>2</sup> 4-Anilido-methylene-1-*o*-tolyl-3-phenyl-5-pyrazolone (one mol) was dissolved in glacial acetic acid and bromine (one mol) added. On standing a heavy yellow crystalline precipitate was formed. This was purified by washing with acetic acid and drying on a porous plate in a desiccator. It melted at 238°.

Calc. for  $C_{22}H_{19}ON_2Br_2$ : Br, 31.17%. Found: 31.05%, 31.58%.

When this dibromide is dissolved in alcohol it undergoes a change, and a new compound containing only one atom of bromine results. It melted at 143° and proved to be identical with the 4-*p*-bromoanilido-methylene-3-phenyl-1-*o*-tolyl-5-pyrazolone. This was also synthesized by heating

<sup>1</sup> *Ann.*, 297, 33 (1897); *THIS JOURNAL*, 31, 1155 (1909); 35, 962, 965 (1913).

<sup>2</sup> *THIS JOURNAL*, 35, 963 (1913).

the pyrazolone and di-*p*-bromo-diphenyl formamidine in kerosene solution. It forms blunt yellow needles, easily soluble in alcohol, melting at 142–3°.

Calc. for  $C_{22}H_{18}ON_2Br$ : N, 9.73%. Found: 9.50%, 10.04%.

For the sake of comparison the corresponding 4-*m*-bromoanilido-methylene-3-phenyl-1-*o*-tolyl-5-pyrazolone was prepared from the pyrazolone and di-*m*-bromodiphenyl formamidine. This is a yellow crystalline compound, that melts at 148–50°, but is not identical with the product obtained from the dibromide.

A yellow dibromide is readily formed when bromine is added to a glacial acetic acid solution of 4-*o*-ethoxyanilido-methylene-1-phenyl-3-methyl-5-pyrazolone. It melts at 203°.

Calc. for  $C_{18}H_{19}O_2N_3Br_2$ : Br, 33.11%. Found: 32.89%, 32.84%.

When this dibromide is crystallized from alcohol, a product separates in orange-yellow needles, that is bromine-free and melts at 179°.

Calc. for  $C_{21}H_{18}O_2N_4$ : N, 15.64%. Found: 15.45%.

The nitrogen corresponds to that required for methenyl-bis-methyl-phenyl-pyrazolone and it was readily identified as that compound.

This unexpected result may be due to the action of hydrobromic acid in the alcohol solution on the anilido compound, since it has been shown earlier in the paper that hydrochloric acid may react with this type of derivatives giving the methenyl-bis-pyrazolones.

This same type of reaction occurred in another instance. Thus in the repetition of a previous experiment when 1-*o*-tolyl-3-phenyl-4-anilido-methylene-5-pyrazolone was dissolved in chloroform and bromine (one mol) added, no precipitate was formed but on evaporating the solvent a yellow bromine addition product was obtained that melted at 238°. When this was treated with alcohol and pyridine a bromine-free compound resulted, which proved to be methenyl-bis-1-*o*-tolyl-3-phenyl-5-pyrazolone (m. p. 181°) identical with the product obtained from *o*-formic ester and the pyrazolone.

**1-*p*-Bromophenyl-3-phenyl-5-pyrazolone.**—When benzoyl acetic ester and the bromophenyl hydrazine are dissolved in alcohol and warmed, there is formed the above pyrazolone. This crystallizes from alcohol in white needles melting at 154–5°.

Calc. for  $C_{18}H_{11}ON_2Br$ : Br, 25.39%. Found: 25.13%.

This compound shows the same general reactions as do the other pyrazolones with free methylene groups. Thus, heated at 120° with benzaldehyde, it yields a brilliant scarlet 4-benzal derivative, which is practically insoluble in the ordinary solvents but dissolves slightly in pyridine but does not melt at 265°.

Calc. for  $C_{22}H_{18}ON_2Br$ : Br, 19.85%. Found: 19.84%, 19.73%.

Heated in kerosene solution at  $125^{\circ}$ , the bromo-diphenyl pyrazolone and diphenyl-formamidine give aniline and 1-*p*-bromophenyl-3-phenyl-4-anilidomethylene-5-pyrazolone, which crystallizes from alcohol in fine, yellow needles, melting point  $188^{\circ}$ .

Calc. for  $C_{22}H_{16}ON_3Br$ : Br, 19.11%. Found: 19.44%.

The methenyl-bis-1-*p*-bromophenyl-3-phenyl-5-pyrazolone results from the interaction of orthoformic ester and the pyrazolone. It crystallizes in reddish yellow needles from pyridine in which it is difficultly soluble. In other solvents it is practically insoluble. It does not melt at  $265^{\circ}$ .

Calc. for  $C_{31}H_{20}O_2N_4Br_2$ : Br, 25.00%. Found: 24.87%.

### Pyrazole Synthesis.

It has been shown that anilido-methylene derivative of the type

$$\begin{array}{c} \text{RC} = \text{O} \\ | \\ \text{R}'\text{C} = \text{CHNHR} \end{array}$$

react in their tautomeric forms with hydrazines yielding substituted pyrazoles as follows:<sup>1</sup>

Additional evidence for this reaction is afforded in the following experiments: *o*-Ethoxy-anilido-methylene-acetoacetic ester and phenyl hydrazine react at water-bath temperature yielding the ethyl ester of 1-phenyl-5-methyl-4-pyrazol-carboxylic ester.<sup>2</sup> The same anilido-methylene compound was heated in alcohol solution with hydrazine sulfate (with the addition of enough alkali to give the free hydrazine). The pyrazol ester first formed was saponified, since there was obtained an acid melting at  $228^{\circ}$ , evidently identical with the 4-methyl-pyrazol-3(5)-carboxylic acid described by Pechmann and Burkhard.<sup>3</sup> They give a melting point of  $218-20^{\circ}$ . However, this condensation with hydrazine alone is being further investigated.

The ethyl ester of benzoyl-acetic acid combines at water-bath temperature with di-*o*-phenetidyl-formamidine to form the *o*-ethoxyanilide of *o*-ethoxyanilido-methylene-benzoyl acetic acid.

The white crystals from alcohol melt at  $173^{\circ}$ .

Calc. for  $C_{28}H_{28}O_4N_2$ : N, 6.51%. Found: 6.91%.

When this anilide is heated with phenyl hydrazine at  $120^{\circ}$ , phenetidine

<sup>1</sup> THIS JOURNAL, 31, 1153 (1909).

<sup>2</sup> Claisen, *Ann.*, 275, 312 (1897).

<sup>3</sup> *Ber.*, 33, 3593 (1900).

is eliminated and there is formed the *o*-ethoxyanilide of 1,5-diphenyl-4-pyrazol-carboxylic acid.

This separated from dilute alcohol in fine needles melting at 118°.

Calc. for  $\text{C}_{24}\text{H}_{21}\text{O}_2\text{N}_3$ : N, 10.97%. Found: 10.54%.

In the course of this investigation several compounds have been prepared, which will be briefly described, as they are not mentioned in the literature.

Di-*o*-phenetidyl formamidine and malonic ester at water-bath temperature gave a good yield of *o*-ethoxyanilido-methylene-diethyl-malonate,  $\text{C}_2\text{H}_5\text{OC}_6\text{H}_4\text{NHCH.C} = (\text{COOC}_2\text{H}_5)_2$ , long needles from 60% alcohol with a melting point of 66–7°.

Calc. for  $\text{C}_{16}\text{H}_{21}\text{O}_6\text{N}$ : N, 4.54%. Found: 4.63%.

1-*o*-Tolyl-3-methyl-4-monobromo-5-pyrazolone is formed when bromine (one mol) is added to a solution of the pyrazolone in glacial acetic acid. The yellow crystals from alcohol melt at 116°.

Calc. for  $\text{C}_{11}\text{H}_{11}\text{ON}_2\text{Br}$ : Br, 29.81%. Found: 30.13%, 29.99%.

1-*o*-Tolyl-3-phenyl-4-monobromo-5-pyrazolone, made in a like manner, crystallizes from alcohol in brownish yellow needles with a melting point of 110°.

Calc. for  $\text{C}_{16}\text{H}_{13}\text{ON}_2\text{Br}$ : Br, 24.29%. Found: 24.44%, 24.54%.

LAWRENCE, KANSAS.

## THE REACTIONS OF SOME CARBOXYL DERIVATIVES OF TRIMETHYLENE.<sup>1</sup>

By DOROTHY A. HAHN.

Received June 3, 1916.

The principal object of this investigation was the study of the products obtained by eliminating hydrobromic acid from bromine substitution products of the esters of anisoyl-phenyl-ethyl-malonic acid. These esters are easily obtained by adding the corresponding malonic esters to phenyl-anisyl-propenone:

They contain one hydrogen atom that is very readily replaced by bromine; the resulting bromine substitution product may be either

<sup>1</sup> Part of a dissertation presented to the Faculty of the Graduate School of Yale University, 1916, in candidacy for the degree of Doctor of Philosophy. The work, suggested by Prof. Elmer P. Kohler of Harvard, was done at Mount Holyoke College, and was accepted at Yale upon recommendation of Prof. Treat B. Johnson.

By cautious treatment with bases it is possible to remove hydrobromic acid from the bromine compound without hydrolyzing much of the ester, the yield being 80 to 87% of bromine-free ester. The main product of this process was always a substance melting at 86°, although an isomeric substance melting at 82° was sometimes obtained in sufficient quantity for separation. For products obtained in this way three formulas are possible.

Between these formulas it is possible to decide by means of the following transformations:

When the ester melting at 86° is treated with alcoholates it forms a metallic derivative that on acidification gives an isomeric ester melting at 82°. This on further action of the same reagent passes into another metallic derivative that yields a third isomer melting at 112°. The structure of this third ester must be represented by the formula

This follows from the fact that on hydrolysis and loss of carbon dioxide, it passes into an acid that can be made synthetically by condensing benzaldehyde with ethyl-β-anisoyl-propionate, and hydrolyzing the product.

The structure of substances obtained by this reaction was established by Borsche.<sup>1</sup>

From this transformation of the ester melting at 86° into a substance with the formula represented by IV, it follows that the former must be a trimethylene compound, and that the relations between the three isomers is represented by the formulas

<sup>1</sup> *Ber.*, 47, 1112 (1914).

II (82°).

III (112°).

All the properties of these three isomers support this conclusion. The substances melting at 82 and 112° readily reduce permanganate while the ester melting at 86° does not. They also, as would be expected, form highly colored metallic derivatives from which they are regenerated by acids, a process that is impossible with the trimethylene compound. That the esters melting at 82 and 112° are stereoisomers is shown also by the fact that the former passes into the latter under the influence of sunlight.

By using aqueous alkalis or alcoholates under special conditions it is possible to hydrolyze the trimethylene compound to the corresponding ester-acid, and then to the dibasic acid.

This was established by esterifying the resulting acids with methyl alcohol and hydrochloric acid—the product in each case being the ester melting at 86°. The trimethylene ring in these acids is not sensitive to bases as it is in the ester, but it opens readily on heating. Thus when the dibasic acid was heated at about 200° it lost carbon dioxide and gave a mixture of products from which four substances, two neutral and two acid, were readily separated. The neutral substances were found to be a green and a yellow unsaturated lactone, so closely related as to suggest geometrical isomerism. The green lactone is the labile form and in recrystallizing from all solvents about one-third passes over into the yellow modification. Both substances dissolve in chloroform and ethyl acetate to give deep red solutions; and in acetone, alcohol and ether to give pale yellow or greenish yellow solutions. The green lactone in solution in acetone reduces permanganate instantly, the yellow lactone does not. Both substances, when dissolved in methyl alcoholic potassium hydroxide and acidified, yield a monobasic unsaturated acid, melting at 165°. This acid, when dissolved in methyl alcohol saturated with hydrogen chloride, passes quantitatively into the yellow lactone.

Both the green and yellow lactones have been obtained by heating a mixture of  $\beta$ -anisoyl-propionic acid, benzaldehyde, and acetic anhydride. As this reaction according to Borsche<sup>1</sup> should give a lactone with the structure

<sup>1</sup> Ber., 47, 1114 (1914).

this formula must represent the isomeric green and yellow lactones; and the corresponding acid must be  $\alpha$ -benzal- $\beta$ -anisoyl-propionic acid,

It is noteworthy that when the dibasic acid is heated, the ring opens to some extent in a different place from that in which it opens when the corresponding ester is treated with an alcoholate:

The ring may be opened in still another way. When the ester melting at  $86^\circ$ , in solution in acetic acid, was reduced with zinc dust, the corresponding ester of anisoyl, phenyl-ethylmalonic acid was obtained:

The acid products obtained as a result of heating the dibasic acid were monobasic acids, melting, respectively, at  $124$  and  $198^\circ$ . The acid melting at  $124^\circ$  was identified as  $\beta$ -benzal- $\beta$ -anisoyl-propionic acid,

It was obtained both as free acid, and as the sodium salt, and was synthesized by the method mentioned in an earlier part of this paper.<sup>1</sup> Both acid and salt reduce potassium permanganate in aqueous solution. The oxidation was attended by the formation of benzaldehyde, and the products of the reaction were identified as benzoic and anisic acids. The acid melting at  $198^\circ$  was obtained only in small quantity. When esterified with methyl alcohol and hydrochloric acid, it gives a solid ester which is identical with one of the products obtained by heating the ester acid,

<sup>1</sup> *Ber.*, 47, 1112 (1914).

### Experimental.

When dimethyl  $\beta$ -anisoyl- $\alpha$ -phenyl ethylmalonate was dissolved in chloroform and treated with a molecular equivalent of bromine, a reaction took place with the evolution of hydrobromic acid, the bromine disappearing as rapidly as added. The chloroform was distilled under diminished pressure and the oily residue dissolved in alcohol. This on evaporation deposited an oil; and all efforts to obtain a solid bromine substitution product failed. The oil, when treated with reagents such as potassium methylate, alcoholic potassium hydroxide, and magnesium methylate, yielded a number of solid isomeric products, which crystallized readily. Three substances melting at 86, 82 and 112° were separated.

The primary product obtained from the bromine derivative of methyl  $\beta$ -anisoyl- $\alpha$ -phenyl-ethylmalonate was a bromine-free ester melting at 86°. Difficulties were experienced in getting good percentage yields of this substance, because of the ease with which it is isomerized in solution. In the first experiments potassium hydroxide was used as the reagent for eliminating hydrobromic acid. An alcoholic solution of the oil obtained in the reaction between methyl anisoyl-phenyl-ethylmalonate and bromine was treated with a 10% solution of potassium hydroxide in equal parts of methyl alcohol and water, the base was added slowly, and the reaction was complete when a yellow color and an alkaline solution remained for a moment after vigorous shaking. The methyl alcohol was then removed by distillation, the residue taken up with ether, and washed with water until free from alcohol. The addition of a few crystals of ester to the dried ethereal solution caused the precipitation of a large part of the ester in almost pure form. In the absence of seed, the separation of a solid product may take place immediately, or it may be necessary to wait weeks for spontaneous crystallization in the resulting oil. The yield of pure solid varied between 30 and 60%. A better average yield was obtained by substituting magnesium methylate for potassium hydroxide. The magnesium compound was added directly to an alcoholic solution of the oil obtained by the action of bromine on methyl anisoyl-phenyl-ethylmalonate. The addition of the base was attended by a change in color varying from salmon to red. Part of the alcohol was removed immediately by distillation and the residue was decomposed with aqueous hydrochloric acid and extracted with ether. The ethereal solution, when washed and dried over calcium chloride, yielded an average of 60 to 70% pure crystalline ester. In all experiments the separation of a solid product was greatly interfered with by the presence of a thick, yellow oil. Residues consisting of this oil deposited additional small quantities of crystals very slowly. The method finally used was a modification of the second and eliminated extraction with ether. 100 g. of

methyl anisoyl-phenyl-ethylmalonate were dissolved in chloroform and treated with 45 g. of bromine. The chloroform was immediately distilled from a water bath under diminished pressure, and the residue, while still hot, was dissolved in a solution of magnesium methylete, prepared by adding 8 g. of magnesium to 200 cc. of alcohol. The magnesium compound was added slowly, with constant shaking, and its addition was attended by an evolution of heat, and by marked changes in color to green, yellow, orange, and finally deep red. A series of parallel experiments showed that the ultimate color of the solution did not influence in any apparent way the quantity nor the quality of the product. The separation of a solid crystalline substance began almost immediately, and was complete within 4 to 12 hrs.; and the yield varied between 82 and 87% of almost pure ester, melting at 82–84°. It was purified by recrystallization from ether.

0.1540 g. subs. and 0.1452 g. subs. gave 0.3866 and 0.3646 g.  $\text{CO}_2$  and 0.0718 and 0.0641 g.  $\text{H}_2\text{O}$ .

Calc. for  $\text{C}_{21}\text{H}_{20}\text{O}_6$ : C, 68.4%; H, 5.4%. Found: C, 68.4, 68.4; H, 5.1, 4.9.

The substance is very soluble in ether acetone, and hot alcohol, slightly soluble in cold alcohol and ligroin. The ester melting at 86° does not reduce permanganate. In solution in carbon tetrachloride it slowly decolorizes bromine with the evolution of hydrobromic acid. Ten grams of substance reacted readily with an equivalent of bromine, but the resulting oil showed no tendency to crystallize even after standing for months. Dissolved in glacial acetic acid and treated with zinc dust and a small quantity of water, the substance passed quantitatively into methyl- $\gamma$ -anisoyl- $\beta$ -phenyl-ethylmalonate.

Under the proper conditions the ester may be hydrolyzed to an ester acid and then to a dibasic acid.

**Methyl Potassium 1-Phenyl-2 Anisoyl Trimethylene Dicarboxate (3-3).**—The pure ester melting at 86° may be hydrolyzed to a neutral monopotassium salt by adding exactly one equivalent of potassium hydroxide to a solution of the ester in five times its weight of methyl alcohol. The base was added slowly as a 25% solution in equal parts of methyl alcohol and water; and the mixture became neutral upon standing from 10 to 12 hrs. in an ice-chest. Since there was no separation of solid product upon standing, the solution was concentrated by evaporation on a water bath. Addition of a small quantity of ether to the cooled solution caused the immediate precipitation of a white crystalline solid.

0.1054, 0.1023 and 0.1025 g. subs. gave 0.0221, 0.0218 and 0.0217 g.  $\text{K}_2\text{SO}_4$ .

Calc. for  $\text{C}_{20}\text{H}_{17}\text{O}_6\text{K}$ : K, 9.94%. Found: K, 9.39, 9.55, 9.49.

The salt is readily soluble in water and in alcohol, insoluble in ether.

It was recrystallized from alcohol-ether mixtures, from which it separates in glistening<sup>a</sup> plates that melt at 152°. At about 170° the substance changes color to a reddish brown and a little above this temperature decomposition with the rapid evolution of CO<sub>2</sub> takes place. When acidified in aqueous solution it gives an oily precipitate which slowly solidifies. When purified this was found to consist of a monobasic acid melting at 162°.

**Methyl-1-phenyl-2-anisoyl-trimethylene Dicarmonic Acid.**—The ester-acid may be prepared by acidifying an aqueous solution of the pure potassium salt; or by hydrolyzing the ester melting at 86° with one equivalent of potassium hydroxide and, after allowing the mixture to stand overnight in a cool place, acidifying with hydrochloric acid. The oil precipitating from acid solution was taken up by chloroform, washed and dried over calcium chloride. The acid crystallizes from chloroform on evaporation, or on the addition of a small quantity of ligroin.

0.1484 and 0.1572 g. subs. gave 0.3674 and 0.3903 g. CO<sub>2</sub>; and 0.0690 and 0.0680 g. H<sub>2</sub>O.

Calc. for C<sub>20</sub>H<sub>18</sub>O<sub>6</sub>: C, 67.7%; H, 5.08%. Found: C, 67.5, 67.7; H, 5.1, 4.8.

The substance crystallizes in large, white prisms, that melt at 162°, and that decompose with the evolution of CO<sub>2</sub> at about 200°. It is very soluble in chloroform, ethyl acetate, and acetone, soluble in ether, and insoluble in ligroin. It may be most readily separated from small quantities of the dibasic acid, occurring as impurities, by recrystallization from chloroform-ligroin mixtures. The basicity of the substance was determined by titration. When dissolved in alcohol and hydrolyzed in the presence of an excess of potassium hydroxide, the acid ester passes into a dipotassium salt, which on acidification gives a dibasic acid, melting at 192°. In alcoholic solutions saturated with hydrogen chloride, it passes quantitatively into the dimethyl ester, melting at 86°. When heated at about 200° the ester-acid loses CO<sub>2</sub>. The reddish brown mass obtained as the result of this action was poured into ether and the ethereal solution was extracted with sodium carbonate. The product was found to be neutral in character. When a small quantity of ligroin was added to the washed and dried ethereal solution, a substance separated slowly, in the form of fine needles or plates. This on recrystallization from ether-ligroin mixtures and finally from methyl alcohol melted at 121°. It was identified as the ester of an acid melting at 198°. The filtrates from which this solid separated were evaporated to dryness on a water bath and were treated with a solution of potassium hydroxide in methyl alcohol. The alkaline solution on dilution with a large quantity of water remained clear, and on acidification with hydrochloric acid, precipitated an oil which slowly solidified. This was found to consist almost entirely of an acid melting at 147° and identified as  $\beta$ -anisoyl-propionic acid.

**Dipotassium 1-Phenyl-2-Anisoyl-trimethylene Dicarbonate (3-3).—**

This substance was obtained by hydrolyzing the ester melting at  $86^{\circ}$  in alcoholic solution with an excess of concentrated aqueous potassium hydroxide. The base was added slowly with constant shaking to the cooled solution of the ester and the salt separated almost immediately in the form of white, glistening plates. It was filtered and washed first with a small quantity of alcohol and then with acetone.

0.1320 g. subs. and 0.1140 g. subs. gave 0.0551 g. and 0.0477 g. of  $K_2SO_4$ .

Calc. for  $C_{19}H_{14}O_6K_2$ : K, 18.7%. Found: K, 18.7, 18.6.

The substance is very soluble in water, sparingly soluble in alcohol and almost insoluble in acetone. Its aqueous solution gave, on acidification, a white, oily precipitate, which slowly solidified, and which consisted of a dibasic acid, melting at  $192^{\circ}$ .

**1 - Phenyl - 2 - anisoyl - trimethylene Dicarmonic Acid (3-3).—**  
 $C_6H_5CH.CHCOC_6H_4OCH_3$ , was obtained by hydrolyzing the dimethyl

ester melting at  $86^{\circ}$  and the ester acid melting at  $162^{\circ}$ , in the presence of excess of concentrated aqueous potassium hydroxide, and acidifying the product. It was also obtained, along with other substances, when the two dimethyl esters, isomeric with the ester melting at  $86^{\circ}$ , were hydrolyzed with potassium hydroxide. Finally it was obtained by the hydrolysis of the corresponding ethyl esters. The oil which separated on acidifying the aqueous solution of the dipotassium salt of this acid, was allowed to solidify, and then washed and dried. It was extracted repeatedly with small quantities of chloroform to remove any acid ester present as impurity, washed once with a very small quantity of ether, and recrystallized from ethyl acetate, or from acetic acid. The pure substance melted at  $192^{\circ}$ , changed in color to a golden brown at about this temperature and at about  $200^{\circ}$  decomposed with the rapid evolution of  $CO_2$ .

0.1497 g. and 0.1226 g. subs. gave 0.3680, 0.3008 g.  $CO_2$ ; and 0.0623, 0.0519 g.  $H_2O$ .

Calc. for  $C_{19}H_{16}O_6$ : C, 67.0; H, 4.7. Found: C, 67.0, 66.9; H, 4.6, 4.7.

The substance is sparingly soluble in water from which it separates slowly in crystalline form. It is very soluble in acetic acid, acetone and ethyl acetate, 1 pt. by weight of substance dissolving in 4, 4, and 14 pts., by weight of these respective solvents. It is slightly soluble in ether, almost insoluble in chloroform, and insoluble in ligroin. It is most readily recrystallized from ethyl acetate-ligroin mixtures from which about 90% of the dissolved substance separates upon cooling. The basicity of the acid was determined by titration with standard alkali. In solution in carbon-bisulfide the substance reacts readily with a molecular equivalent

of bromine with the evolution of hydrobromic acid, but no solid was separated from the resultant oil. In solution in methyl alcohol saturated with hydrogen chloride, the acid passes readily into the methyl ester melting at  $86^{\circ}$ . Heated above  $200^{\circ}$  the acid decomposes with the evolution of carbon dioxide. Two neutral and two acid products were obtained as a result of this decomposition, which will be considered later on in this paper.

**1-Phenyl-2-anisoyl-trimethylene Dicarmonic Acid (3-3)** was also obtained by hydrolyzing the corresponding monoethyl ester. The diethyl ester was never isolated, so that a description of this ester-acid and its salt may be considered at this point.

**Ethyl Potassium 1-Phenyl-2-anisoyl Trimethylene Dicarboxate (3-3)**,  $C_6H_5CH-CHCOC_6H_4OCH_3$ , was obtained by treating diethyl ( $\beta$ -bromo- $\beta$ -

anisoyl- $\alpha$ -phenyl-ethyl) malonate<sup>1</sup> in alcoholic solution with two equivalents of potassium hydroxide. The alkali was added as a 25% solution in equal parts of alcohol and water, and the mixture was allowed to stand overnight. The solution was then concentrated and allowed to cool when a small quantity of ether was added. The salt separated slowly in the form of large colorless hexagonal prisms.

0.0987, 0.1207 g. subs. gave 0.0204 and 0.0250 g.  $K_2SO_4$ .

Calc. for  $C_{21}H_{19}O_6K$ : K, 9.60%. Found: K, 9.26, 9.28.

The substance is very soluble in water and in alcohol. Its aqueous solution is neutral to litmus.

**Ethyl-1-phenyl-2-anisoyl Trimethylene Dicarboxate Acid (3-3)** may be prepared by acidifying an aqueous solution of the corresponding potassium salt. The reaction is quantitative. The substance separates in the form of an oil which solidifies on standing, but which is most conveniently extracted with ether. The ester-acid separates from the dry ethereal solution on evaporation, or on the addition of a small quantity of ligroin in the form of large, colorless hexagonal prisms.

0.1449 and 0.1556 g. subs. gave 0.3622 and 0.3882 g.  $CO_2$ ; and 0.0737, 0.0786 g.  $H_2O$ .

Calc. for  $C_{21}H_{18}O_6$ : C, 68.4%; H, 5.4%. Found: C, 68.1, 68.0; H, 5.6, 5.6.

The substance is very soluble in chloroform, quite soluble in ether and insoluble in ligroin. Its basicity was determined by titration. When hydrolyzed in the presence of an excess of potassium hydroxide it passes into a dipotassium salt, which on acidification gives a dibasic acid melting at  $192^{\circ}$  and identified as 1-phenyl-2-anisoyl-trimethylene dicarmonic acid (3-3).

<sup>1</sup> *Am. Chem. J.*, 49, 178 (1913).

When the ester melting at  $86^{\circ}$  was treated with alcoholates it formed a metallic derivative which on acidification gave an isomeric ester melting at  $82^{\circ}$ . This on further action of the same reagents gave a third isomer melting at  $112^{\circ}$ .

**Methyl  $\beta$ -Benzal- $\beta$ -Anisoyl-methylmalonate** (II and III, p. 1520), M. p.  $82^{\circ}$  and  $112^{\circ}$ .—The labile form of this ester, melting at  $82^{\circ}$ , was prepared by adding a few drops of sodium methylate to a well cooled ethereal solution of the ester melting at  $86^{\circ}$ . The separation of a solid metallic derivative took place slowly. This consisted of fine, yellow needles which were filtered and washed with ether. It was decomposed by shaking with ether and cooled hydrochloric acid; and the colorless ethereal solution, after being washed free from acid and dried over calcium chloride, gave an almost pure product melting at  $82^{\circ}$ . The yield varied between 30 and 50%. This was improved by modifying the method, magnesium methylate being substituted for sodium methylate, when a yield varying between 70 and 90% was obtained. The procedure in this case was as follows: 1.3 grams of magnesium were dissolved in 27 cc. of methyl alcohol to which a small quantity of mercuric chloride had been added. At the conclusion of this reaction, 10 g. of the ester melting at  $86^{\circ}$  were added to the mixture in small quantities, and in the form of a fine powder; and its solution took place immediately. The solution was heated on the water bath for about an hour, part of the alcohol was then distilled off, and the residue shaken with ether and cooled hydrochloric acid. The ethereal solution after being washed free from acid and dried over calcium chloride, deposited a crystalline solid melting at  $82^{\circ}$ . This substance was finally purified by recrystallization from ether and alcohol.

0.1373 and 0.1671 g. subs. gave 0.3486 and 0.4249 g.  $\text{CO}_2$ ; and 0.0629, 0.0755 g.  $\text{H}_2\text{O}$ .  
Calc. for  $\text{C}_{21}\text{H}_{20}\text{O}_6$ : C, 68.4; H, 5.4. Found: C, 69.2, 69.3; H, 5.0, 5.0.

The substance is extremely soluble in ether and in hot methyl alcohol. It crystallizes from both solvents in the form of long, fine needles, which appear soft and felt-like while moist, but which dry in hard lumps. It readily reduces potassium permanganate in solution in acetone. In solution in chloroform or carbon tetrachloride, the substance reacts readily with a molecular equivalent of bromine. The reaction was attended by the evolution of hydrobromic acid, but the resulting oil showed no tendency to form a solid product. When the ester in solution in methyl alcohol was treated with an equivalent of potassium hydroxide dissolved in the same solvent, the separation of a deeply colored metallic derivative took place at once. The substance crystallized in the form of coarse, orange-colored needles, which were filtered, washed with alcohol, and analyzed.

0.0730, 0.0831 and 0.0904 g. subs. gave 0.0149, 0.0170 and 0.0185 g.  $K_2SO_4$ .  
Calc. for  $C_{21}H_{19}O_6K$ : K, 9.6%. Found: K, 9.15, 9.17, 9.17.

The substance is insoluble in water and ether, but dissolves readily in alcohol forming deep red solutions. The solution in alcohol is very unstable, and the color was completely discharged upon standing, or upon boiling the solutions. When the dry metallic derivative was shaken with ether and hydrochloric acid, it passed back quantitatively into the ester, melting at  $82^\circ$ .

The stable form of  $\beta$ -benzal- $\beta$ -anisoyl-methylmalonate, m. p.  $112^\circ$ , was formed by the action of sunlight on an ethereal solution of the low melting ester, in the presence of a small quantity of iodine. The transformation was quantitative. The same substance was obtained by treating the ester, m. p.  $82^\circ$ , with sodium and magnesium methylates and decomposing the product with hydrochloric acid. Since the yield was better in the case of the latter reagent, the procedure in this case will be described. Magnesium methylate was prepared by dissolving 1.3 g. magnesium in 27 cc. methyl alcohol. As soon as the reaction was complete, 10 g. of ester were added to the solution in the form of a fine powder. Either of the isomeric substances, melting at  $86$  and  $82^\circ$  could be used for this reaction. The substance dissolved on warming, and the resulting mixture was evaporated to dryness on a water bath. If the dried residue appeared greenish or yellow, a small quantity of alcohol was added and the mass was again evaporated to dryness. This process was repeated until the product appeared white. The mass was then decomposed by shaking with ether and cooled hydrochloric acid, when the final product, which is sparingly soluble in ether, separated in crystalline form. It was filtered, washed with ether and dried. It was further purified by recrystallizing from chloroform-ether mixtures. The yield varied between 80 and 90%.

0.1628, 0.1701 and 0.1547 g. subs. gave 0.4100, 0.4293, 0.3913 g.  $CO_2$ , and 0.0743, 0.0747, 0.0683 g.  $H_2O$ .

Calc. for  $C_{21}H_{19}O_6$ : C, 68.4%; H, 5.4%. Found: C, 68.7, 68.8, 68.9; H, 5.1, 4.9, 4.9.

The substance is very soluble in chloroform, soluble in hot alcohol, sparingly soluble in cold alcohol, and almost insoluble in ether. It separates from chloroform-ether mixtures, or from solutions in hot alcohol, in the form of large, well-defined prisms. Dissolved in chloroform or carbon tetrachloride, it readily reacts with an equivalent of bromine. The reaction was attended by an evolution of hydrobromic acid, but the resulting oil gave no solid product. A solution of the substance in acetone immediately reduced permanganate in solution in the same solvent. Subjected to prolonged heating with magnesium methylate, it suffered no change and was regenerated quantitatively when shaken with ether

and hydrochloric acid. When the ester in solution in methyl alcohol was treated with potassium hydroxide dissolved in the same solvent, a highly colored metallic derivative was formed. This substance separated immediately in the form of long, fine, yellow needles, which were soft and felt-like while moist. It was filtered, washed with ether, and analyzed.

0.0991, 0.1173, 0.1420 g. subs. gave 0.0196, 0.0232 and 0.0280 g.  $K_2SO_4$ .

Calc. for  $C_{21}H_{19}O_6K$ : K, 9.6%. Found: K, 8.87, 8.87, 8.84.

The substance is insoluble in water and in ether, but is very soluble in alcohol. Like its isomer it is very unstable in solution, the deep red color of its alcoholic solutions being quickly discharged even upon standing in the cold. The dried substance, when shaken with ether and hydrochloric acid, passed back quantitatively into the ester, melting at  $112^\circ$ .

When the esters melting at  $82$  and  $112^\circ$ , in solution in alcohol, are hydrolyzed by concentrated aqueous potassium hydroxide, the metallic derivative which at first forms, dissolves on standing or upon boiling. The resulting straw-colored liquid was poured into water in a separatory funnel, and extracted repeatedly with ether. The ether when washed, dried and evaporated, left no residue, showing the absence of any neutral product, and showing also that the original ester had been completely hydrolyzed. The alkaline solution when acidified precipitated a yellow oil. This was found to consist of a mixture of acids, three of which were finally separated and identified. They were 1-phenyl-2-anisoyl-trimethylene dicarbonic acid (3-3), m. p.  $192^\circ$ ;  $\beta$ -anisoyl-propionic acid, m. p.  $147^\circ$ ; and  $\beta$ -benzal- $\beta$ -anisoyl-propionic acid, m. p.  $124^\circ$ . The first was found to be identical with the dibasic acid obtained by the hydrolysis of the ester melting at  $86^\circ$ . The second and third were acids whose identity was established by syntheses to be described later in this paper.

Both the dibasic acid and the ester-acid, obtained by hydrolyzing the ester, m. p.  $86^\circ$ , lose carbon dioxide when heated at about  $200^\circ$ . The result of the decomposition of the first named substance was a mixture from which four solid products were isolated.

When the acid, melting at  $192^\circ$ , was heated at about  $210^\circ$ , it was decomposed with an evolution of carbon dioxide. At the same time it changed color first to amber and then to greenish brown. When gas was no longer evolved, the product was poured at once into a small quantity of alcohol-free ether. The mixture dissolved at once in the ether, but in the course of a few moments the separation of a greenish brown precipitate took place. The precipitate consisted of a mixture of three substances, all of which are very sparingly soluble in ether. The pre-

precipitate was filtered, washed with ether and the products separated by fractional crystallization from ethyl acetate. They consisted of a yellow and a green unsaturated lactone, melting at about 173 and 176°, respectively; and of a monobasic acid melting at 198°. After the separation of these substances, the filtrates contained in ethyl acetate and ether were combined, and the mixture was then extracted repeatedly with dilute sodium carbonate in order to remove the acid products. The ethereal solution containing neutral substances was then washed, dried and allowed to evaporate. It gave an oil from which small quantities of the yellow lactone slowly crystallized. No other solid product was separated. Since this oil represented at least 80% of the original dibasic acid, the attempt was made to study it by dissolving it in sodium methylate and then acidifying. The oil was readily soluble in this reagent, and the solution on dilution with water remained clear. The addition of hydrochloric acid to the aqueous solution caused the precipitation of a yellow oil which was found to consist in large part of  $\beta$ -anisoyl-propionic acid. The identification was made by comparison with a specimen of this acid obtained by synthesis.

The sodium carbonate extracts were combined and extracted once with ether. Either of two subsequent methods of procedure were employed—favoring, respectively, the separation of one or the other of two monobasic acids whose sodium salts were present in the alkaline solution. (a) The aqueous solution containing sodium carbonate was acidified with hydrochloric acid. A yellow oil was precipitated which partially solidified on standing. The acid solution was decanted, the oil was washed with water and allowed to stand until it seemed quite dry. The addition of a small quantity of alcohol-free ether caused the immediate separation in crystalline form of additional small quantities of the acid melting at 198°. It was necessary to handle the material very quickly at this point, and to filter the acid at once; since, upon standing, it passed into solution in ether, the ethereal solution on evaporation giving an oil which showed no tendency to crystallize. (b) The aqueous solution containing sodium carbonate was evaporated to dryness on a water bath, and the residue was extracted repeatedly with small quantities of alcohol in order to remove any soluble salts of organic acids. The alcoholic extracts were then combined, concentrated by evaporation on a water bath, and, when cool, treated with a small quantity of ether. The addition of ether caused the immediate precipitation of a white crystalline substance, and further small additions of ether increased the quantity of this substance. It was filtered, washed with a small amount of acetone, and recrystallized from alcohol or from alcohol-ether mixtures. It was found to consist of a salt, melting at 212°, and its aqueous solution, on addition of hydrochloric acid, gave an unsaturated monobasic acid melting at 124°. The

filtrates from this salt were combined, concentrated on a water bath, diluted with water and acidified. The precipitated oil was taken up with ether, the ether washed, dried, and evaporated. It deposited an oil which showed no tendency to crystallize.

Two substances corresponding to this formula were formed when 1-phenyl-2-anisoyl-trimethylene-dicarboxylic acid (3-3) was heated above 200°. In a series of five parallel experiments, using 20 g. portions of the same specimen of dibasic acid, and varying the temperature between 210 and 250°, it was found that the quantity of colored lactone obtained remained almost constant and corresponded to about 4% of the acid used in the experiment. Quick heating at 230° gave the best yield of solid product when poured into ether, and, therefore, the best yield of the acid melting at 198°. The lactones were readily separated from the acid product by recrystallizing from ethyl acetate. Both substances were prepared by synthesis by methods analogous to those used by Borsche in preparing 1-benzal-3-phenyl-croton-lactone.<sup>1</sup> 18.6 g. of pure sodium  $\beta$ -anisoyl-propionate and 12 g. of benzaldehyde were heated with 24 g. of acetic anhydride in a metal bath at a temperature between 110 and 115° for 24 hrs. The mixture while still hot was treated with 200 cc. of alcohol, allowed to cool, and then filtered, and washed with alcohol. After crystallization from ethyl acetate it gave 5.2 g. of green lactone, m. p. 168-170°. In recrystallizing this, the filtrates yielded the yellow modification. Other products separated from the mother liquors were sodium  $\beta$ -anisoyl-propionate, 7.8 g., and free  $\beta$ -anisoyl-propionic acid, 3.8 g. The reaction thus took place entirely in one sense, although only about one-third of the original salt reacted with benzaldehyde. The lactones obtained in this way were identical in every respect with those obtained by heating the dibasic acid. The relation existing between the green and yellow lactone is very interesting, the results of analysis showing them to be isomeric substances.

0.1012 and 0.1392 g. subs. (yellow) gave 0.2865, 0.3944 g. CO<sub>2</sub>; and 0.0459, 0.0621 g. H<sub>2</sub>O.

0.1261 g. subs. (green) gave 0.3583 g. CO<sub>2</sub> and 0.0589 g. H<sub>2</sub>O.

Calc. for C<sub>18</sub>H<sub>14</sub>O<sub>3</sub>: C, 77.6%; H, 5.0%. Found: C, 77.2, 77.2, 77.4; H, 5.0, 4.9, 5.1.

Both substances melt to a deep red liquid, both dissolve in chloroform and ethyl acetate to give deep red solutions, in acetone alcohol and ether to give yellow or pale greenish yellow solutions. One gram of substance dissolves in 38 g. of ethyl acetate, 66 g. acetone, 14 g. chloroform, and 500

<sup>1</sup> Ber., 47, 1114 (1914).

g. ether, respectively. In recrystallizing from all solvents about one-third of the green lactone passes over into the yellow modification. Both substances crystallize from all solvents in the form of long, glistening plates. In the matter of chemical properties the only point of difference observed was that the green modification instantly reduced permanganate in solution in acetone, while the yellow form did not. Both dissolve in alcoholic potassium hydroxide, and sodium methylate; and these solutions, when diluted with water and acidified, gave the same acid. This acid, when recrystallized from chloroform-ligroin mixtures, melted at  $165^{\circ}$ . It corresponds to  $\alpha$  phenylacetyl-cinnamic acid, obtained in an analogous manner by Borsche.

**$\alpha$ -Benzal- $\beta$ -anisoyl-propionic Acid,**  $C_6H_5CH = C.CH_2COC_6H_4OCH_3$ ,  

|  
COOH

was obtained from the corresponding crotonlactone in the manner described. It separated from aqueous alkaline solutions as a fine, white flocculent precipitate on the addition of acid. This was filtered, washed with water and dried. It was recrystallized first from chloroform-ligroin mixtures, and then from acetone from which it separated in long, hexagonal prisms.

0.1099 g. subs. gave 0.2938 g.  $\text{CO}_2$  and 0.0523 g.  $\text{H}_2\text{O}$ .

Calc. for  $C_{18}H_{16}O_4$ : C, 72.9; H, 5.4. Found: C, 72.9; H, 5.3.

The substance is sparingly soluble in water. Its aqueous solution reacts acid toward litmus and reduces permanganate instantly in the cold. The acid dissolves readily in chloroform, ethyl acetate, acetone, and ether, but is almost insoluble in ligroin. In solution in carbon bisulfide it readily decolorizes bromine with the evolution of hydrobromic acid. Its solution in methyl alcohol, when saturated with hydrogen chloride, gives an immediate precipitation of the corresponding yellow crotonlactone, m. p. 173°.

**$\beta$ -Benzal- $\beta$ -anisoyl-propionic Acid**,  $\text{C}_6\text{H}_5\text{CH} = \text{C}.\text{COC}_6\text{H}_4\text{OCH}_3$ .—This

$$\begin{array}{c} | \\ \text{CH}_2\text{COOH} \end{array}$$

acid, m. p. 124°, was formed together with an isomeric acid, m. p. 198°, when 1-phenyl-2-anisoyl-trimethylene dicarbonic acid (3-3) was heated at above 200°. It was separated from the other substances formed as a result of this reaction by means of its sodium salt and in the manner already described. The substance was also prepared by synthesis. The method used was analogous to that employed by Borsche in the preparation of benzoyl-phenyl-isocrotonic acid<sup>1</sup> ( $\beta$ -benzal- $\beta$ -benzoyl-propionic acid). 1.47 g. of sodium in 30 cc. absolute alcohol were cooled with ice-water, and added drop by drop, with constant shaking, to a mixture of

<sup>1</sup> *Ber.*, 47, 1112 (1914).

15 g. of ethyl  $\beta$ -anisoyl-propionate and benzaldehyde. There was no heat evolved during this reaction so far as could be observed. The mixture was allowed to stand overnight and in the morning showed the separation of a solid substance in the form of a white, flaky precipitate. This was filtered and washed, first with alcohol, and then with acetone. When dry it dissolved in water to give a clear solution and this on addition of hydrochloric acid gave an oily precipitate. This, when washed, dried, and recrystallized, gave an acid melting at  $124^{\circ}$ . This acid was the only substance that was separated in pure form as a result of this condensation. This yield was, however, very unsatisfactory, since only about 25% of solid product was obtained, the remaining 75% being accounted for as an oil which showed no tendency to crystallize. The acid was purified by crystallization from chloroform-ligroin mixtures and then from acetone from which it separated in long, hexagonal prisms.

0.1496 and 0.1694 g. subs. gave 0.3951, 0.4475 g.  $\text{CO}_2$ ; and 0.0704, 0.0803 g.  $\text{H}_2\text{O}$ .  
Calc. for  $\text{C}_{18}\text{H}_{16}\text{O}_4$ : C, 72.9%; H, 5.4%. Found: C, 72.0, 72.0; H, 5.2, 5.2.

The substance is soluble in ether, chloroform, ethyl acetate and acetone, 1 g. of substance dissolving in 15, 8, 6 and 2.4 g. of these solvents, respectively. It is insoluble in ligroin and only slightly soluble in hot water, from which it crystallizes on cooling. Its aqueous solution gives an acid reaction with litmus and reduces permanganate instantly in the cold. When dissolved in methyl alcohol saturated with hydrogen chloride, it passes into an oil. This oil showed no tendency to crystallize after standing for months.

**Sodium  $\beta$ -Benzal- $\beta$ -anisoyl-propionate** was obtained when phenyl-anisoyl-trimethylene dicarbonic acid was decomposed and the product treated in the manner described. It was purified by repeated recrystallizations from alcohol, and from alcohol-ether mixtures, from which it separated in the form of soft, white needles melting at  $212^{\circ}$ .

0.1805 and 0.1515 g. subs. gave 0.0368 and 0.0307 g.  $\text{Na}_2\text{SO}_4$ .  
Calc. for  $\text{C}_{18}\text{H}_{16}\text{O}_4\text{Na}$ : Na, 7.32%. Found: Na, 6.60, 6.56.

The salt is very soluble in water and in hot alcohol, less soluble in cold alcohol, and insoluble in ether. Its aqueous solution when acidified with hydrochloric acid deposited a white oil, which crystallized on standing and which consisted of pure  $\beta$ -benzal- $\beta$ -anisoyl-propionic acid. An aqueous solution of the salt reduced permanganate as rapidly as added. The reaction was accompanied by the liberation of benzaldehyde which was recognized by its odor. The products of the reaction were readily separated and identified as benzoic and anisic acids.

**1-Phenyl-2-anisoyl-trimethylene-3-monocarbonic Acid,**

This acid was obtained in very small quantities along with  $\beta$ -benzal- $\beta$ -anisoyl-propionic acid\* as a result of heating the dibasic acid. It was separated as one of a number of substances formed when methyl  $\gamma$ -bromo- $\gamma$ -anisoyl- $\beta$ -phenyl-butyrate<sup>1</sup> was heated with dimethyl aniline. It was obtained in the form of its methyl ester when the ester acid, m. p.  $162^\circ$ , was heated above  $200^\circ$ . The acid was purified by recrystallizing from acetone and ethyl acetate and washing with ether. It crystallized from acetone in the form of prisms, m. p.  $198^\circ$ .

0.1207 and 0.1108 g. subs. gave 0.3230 and 0.2958 g.  $\text{CO}_2$ ; and 0.0576, 0.0529 g.  $\text{H}_2\text{O}$ .  
Calc. for  $\text{C}_{18}\text{H}_{16}\text{O}_4$ : C, 72.9%; H, 5.4%. Found: C, 72.9, 72.8; H, 5.3, 5.3.

The substance is sparingly soluble in ether, chloroform, ethyl acetate and acetone, 1 g. of substance dissolving in 514, 87, 35 and 15 g. of these solvents, respectively. It is slightly soluble in water, its aqueous solution giving an acid reaction with litmus. In solution in carbon tetrachloride it decolorized bromine with the evolution of hydrobromic acid. Its solution in methyl alcohol saturated with hydrogen chloride deposited a crystalline ester on standing.

was formed from the corresponding acid in the method just described. It was also obtained as a result of heating the ester-acid, m. p.  $162^\circ$ , at about  $200^\circ$ . It was purified by ether-ligroin mixtures, and finally by recrystallizing from methyl alcohol.

0.1364 and 0.1260 g. subs. gave 0.3657, 0.3382 g.  $\text{CO}_2$  and 0.0678, 0.0624 g.  $\text{H}_2\text{O}$ .  
Calc. for  $\text{C}_{18}\text{H}_{16}\text{O}_4$ : C, 73.5%; H, 5.8%. Found: C, 73.1, 73.2; H, 5.5, 5.5.

The substance is very soluble in ether and in hot methyl alcohol, less soluble in cold alcohol, and sparingly soluble in ligroin. It crystallizes in the form of soft, white, glistening needles, melting at  $121^\circ$ . When dissolved in alcoholic potassium hydroxide and poured into water the solution remained clear, but on acidifying with hydrochloric acid, precipitated an oil which partially solidified upon standing. The solution was decanted, the oil was washed and allowed to stand until it appeared quite dry. The addition of a small quantity of ether caused the separation of a white crystalline solid, which was filtered at once and washed with ether. It consisted of the acid, m. p.  $198^\circ$ .

**$\beta$ -Anisoyl-propionic Acid**,  $\text{CH}_3\text{OC}_6\text{H}_4\text{CO}\cdot\text{CH}_2\text{CH}_2\text{CO}_2\text{H}$ , was obtained as one of the decomposition products formed when the unsaturated methyl esters melted at  $82^\circ$  and  $112^\circ$ , respectively, were hydrolyzed in the presence of an excess of aqueous potassium hydroxide. It was also obtained from residues that had stood for some time after the separation of the main products formed by heating the dibasic acid. It was prepared

<sup>1</sup> *Am. Chem. J.*, 49, 177 (1913).

synthetically by a method analogous to that used by Borsche in the preparation of  $\beta$ -benzoyl-propionic acid.<sup>1</sup> One part anisole was added to 1 part succinic anhydride and 1.5 parts  $\text{AlCl}_3$  suspended in 4 parts carbon disulfide. The mixture was heated on a water bath until hydrogen chloride was no longer evolved. The dark red semisolid addition product was decomposed with ice, when a white, insoluble product was obtained. The crude product was dried, and was finally purified by preparing ethyl- $\beta$ -anisoyl propionate, recrystallizing it, and from it, regenerating the acid. This was then further purified by recrystallizing from acetone, from which it separated in large hexagonal prisms, m. p.  $147^\circ$ .

0.1354 and 0.1318 g. subs. gave 0.3141, 0.3058 g.  $\text{CO}_2$ ; and 0.0623, 0.0614 g.  $\text{H}_2\text{O}$ ; (recrys.) 0.1344 g. gave 0.3136 g.  $\text{CO}_2$  and 0.0663 g.  $\text{H}_2\text{O}$ .

Calc. for  $\text{C}_{11}\text{H}_{12}\text{O}_4$ : C, 63.4%; H, 5.7%. Found: C, 63.2, 63.2, 63.6; H, 5.1, 5.1, 5.4.

The acid is sparingly soluble in most organic solvents, one part dissolving in 54 parts acetone, 48 parts ether, 36 parts ethyl acetate and 30 parts methyl alcohol. It is soluble in hot water, 15 parts of substance dissolving in 800 parts of solvent, from which about 90% crystallizes on cooling. Its solutions in methyl and ethyl alcohol, when saturated with hydrogen chloride, gave the corresponding esters. These melted at  $47^\circ$  and  $52^\circ$ , respectively. Both are very soluble in alcohol and ether, but may be readily purified by recrystallization from their respective alcohols, from which they crystallize in large colorless crystals. The acid contains hydrogen that is exceedingly sensitive to oxidizing agents, and its sodium salt reduces permanganate solution instantly in the cold. The products of this oxidation were anisic acid, and another acid product which was not fully studied. It was very soluble in water, from which, however, it was readily extracted by ether. The dried ethereal solution on evaporation deposited the acid in the form of large, glistening, white plates, but the substance was so extremely sensitive that its solution in ligroin decomposed with the deposition of carbon when evaporated on the water bath.

## THE MONONITRO PHENYL ETHERS.

BY HILTON IRA JONES AND ALFRED N. COOK.

Received April 25, 1916.

In 1873 Maikopar<sup>2</sup> made a dinitrophenyl ether by heating dinitrochlorobenzene, caustic potash and phenol in alcoholic solution. These substances react according to the following equation:

<sup>1</sup> *Ber.*, 47, 1110 (1914).

<sup>2</sup> *Ibid.*, 6, 564 (1873).

Maikopar seems to have been the first chemist to use this general method, which has been brought into prominence by the work of Willgerodt, Haeussermann, Ullmann and Cook.

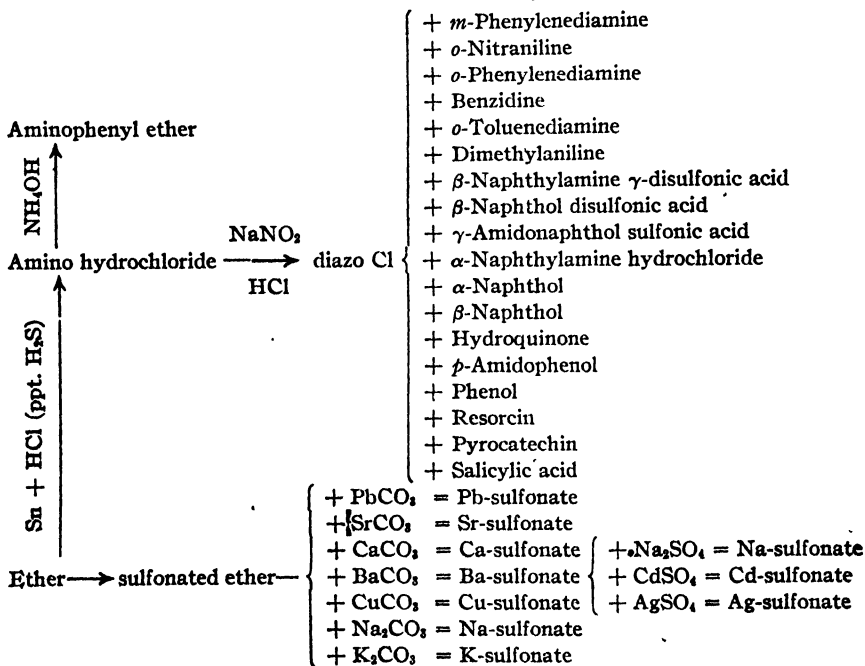

The presence of the negative nitro group makes it much easier to manufacture the nitrophenyl ethers than the corresponding non-nitro compounds. An increasing number of negative groups seems to enhance this effect. Thus picryl chloride and potassium phenolate give a much better yield than the phenolate with either *o*- or *p*-bromonitro benzene. The position of the nitro group in reference to the halogen also has a marked effect both on the stability of the substance and the yield as well as the ease of production. Thus, following the usual rule, a *m*-bromonitro benzene will scarcely react with potassium phenolate at all unless a catalytic agent be present, and the ortho compound reacts more easily than the para, the reaction going to completeness on the boiling water bath in case of the ortho compound, while it requires a temperature of 135 to 140° for the para. The yield of ether produced is greater in case of the ortho, though if it is freed from the other reaction products by distillation, it is liable to be less because of its greater instability and consequent decomposition at a higher temperature. Performed in this way we have obtained from the para compound 81% of the theoretical yield of ether, and from the ortho compound 67%. But if, instead of separating by distillation, the reaction compound is extracted with ether, sulfonated and converted into the potassium salt, the yield in case of the ortho compound was 85% of the theory, while the yield in case of the para compound was 82%. The para compound reduces much more easily than the ortho. It is sometimes very difficult to isolate these in pure form. These amino compounds in turn may be diazotized and converted into a large number of dyes, or the amino ethers may be coupled with other diazonium compounds with similar results. The ortho amino and diazonium compounds are much more unstable than the corresponding para compounds. The ortho aminophenyl ethers yield the more brilliant shades as well as the widest variety of colors. The shades of the sulfonated dyes seem somewhat less brilliant than the unsulfonated. The ortho nitrophenyl ethers are readily converted into the sulfonic acids by treatment with concentrated sulfuric acid in the cold. The para compounds sulfonate with greater difficulty, treatment with sulfuric acid on the boiling water bath being necessary. The para compounds are uniformly better crystalline than the ortho, less soluble and without exception melt and distil at higher temperatures. The *p*-nitrophenyl ether is beautifully crystalline and readily sublimes, while all efforts to reduce the *o*-nitrophenyl ether to a crystalline state by cooling far below zero have failed.

## Experimental Part.

TABLE I.

## General Outline.

## I. The Unsulphonated Dyes.

## General Outline.

## II. The Sulfonated Dyes.

**Potassium Phenolate.**—In the earlier experiments of Maikopar<sup>1</sup> and Willgerodt,<sup>2</sup> an alcoholic solution of potassium hydroxide and phenol was employed. In one of his experiments he also used carbon bisulfide as a solvent. Haeussermann and Teichmann<sup>3</sup> were the first to use potassium phenolate with phenol as a menstruum. They made the potassium phenolate by treating phenol with metallic potassium in an atmosphere of hydrogen. For use in preparing various phenyl ethers, Cook<sup>4</sup> made potassium phenolate by dissolving both phenol and alkali in a small amount of water, evaporating to dryness on a water bath and heating to 100° in an air bath. In later experiments he made the potassium phenolate without the use of any water and showed<sup>5</sup> that better yields are obtained by using the phenolate made with KOH and phenol. Our recent work confirms this conclusion. We have found the most convenient way of preparing potassium phenolate is to take 50 g. of phenol and 35 g. of potassium hydroxide, purified by alcohol, and melt each separately with the smallest possible amount of heat. The molten hydroxide is then poured with active stirring into the molten phenol and the product heated on a low flame with constant stirring until it just begins to form a hard ball on the rod. It is removed and placed in a flask and tightly corked. It is best to powder it while hot. This method gives a snow-white product free from the objectionable charring which usually occurs. This method is applicable to the preparation of various phenolates except when they contain one or more nitro groups, in which case they ignite spontaneously.

***o*-Nitrophenyl Ether.**—13.2 grams of potassium phenolate prepared as above are mixed with 20.2 g. of powdered *o*-bromonitro benzene, being one-tenth gram molecule of each, heated for two hours on a boiling water bath until the reaction compound is of a homogeneous reddish brown color and granular appearance. All the earlier workers in making the phenyl ethers by this method thought it necessary to use some substance as a menstruum—alcohol, carbon bisulfide or phenol. We now know that the use of any menstruum is in some cases unnecessary and in others harmful. The reaction product is not extracted with ether as was done by the early experiments, but distilled directly *in vacuo*. On redistillation the pure *o*-nitrophenyl ether is obtained, boiling at 195 to 197° under 45 mm. pressure<sup>6</sup> with partial decomposition. It boils without decomposition at 13 mm. pressure. A sample was seven times distilled and reduced to a temperature of —80° with solid carbon dioxide and ether. Under these

<sup>1</sup> *Ber.*, 6, 564 (1873).

<sup>2</sup> *Ibid.*, 12, 762 and 1277 (1879); 13, 887 (1880).

<sup>3</sup> *Ibid.*, 29, 1446 and 2083 (1896); 30, 738 (1897).

<sup>4</sup> *Am. Chem. J.*, 24, 525 (1902).

<sup>5</sup> *THIS JOURNAL*, 25, 60 (1903).

<sup>6</sup> Haeussermann and Teichmann give the boiling point as 205° at 45 mm. and Ullmann 185° at 55 mm.

conditions the liquid became very viscous, but showed no signs of crystallization. Ortho nitrophenyl ether has a pleasing, characteristic, ethereal odor. It is very soluble in alcohol, ether, benzene, xylene, toluene, carbon bisulfide and chloroform. It is but slightly soluble in ligroin and entirely insoluble in water. Its specific gravity at  $21.5^{\circ}$  is 1.2539. The ether shows the peculiar property of not wetting glass, but draws away from it like water from a glass that is oily. The surface tension was found to be 0.6225, as compared with water, and 44.882, absolute. The viscosity was 13.17, as compared with water, and 6.664, absolute, both being determined at  $25^{\circ}$ . The refractive index<sup>1</sup> at  $20^{\circ}$  is 1.575. The ether when freshly distilled is a golden yellow color, but shows signs of darkening on long standing.

**The Free Sulfonic Acid,** ( $\text{NO}_2\text{C}_6\text{H}_4\text{OC}_6\text{H}_4\text{SO}_3\text{H}$ ).—The free sulfonic acid of *o*-nitrophenyl ether was prepared from the corresponding cadmium sulfonate (*q. v.*) by dissolving this salt in hot water, precipitating the cadmium with hydrogen sulfide and removing the water from the solution by distillation *in vacuo*. When the solution had been reduced to very small volume it was removed and placed in an evaporating dish in a vacuum desiccator over sulfuric acid. After a few hours the free sulfonic acid crystallized out in glistening white flakelets which grouped themselves together in radial systems resembling hoar frost. These crystals on exposure to the air soon liquefied, and if exposed to the light, lose their luster and darken. The crystals melt at  $90^{\circ}$  with decomposition. When a water solution of the acid is added to a soda solution, a brisk effervescence results. The free acid is unstable, very hygroscopic and extremely soluble. An analysis was not attempted because of this hygroscopic character.

**The Sulfonic Acid Salts.**—The sulfonic acid salts of *o*-nitrophenyl ether were prepared in two ways. First, the ether was sulfonated by treating with three volumes of concentrated sulfuric acid. This was warmed for thirty minutes on a water bath. The ether turns red during this process and complete solution takes place. As soon as the ether is completely sulfonated the reaction product is poured into a large excess of water. The whole is heated to boiling and completely neutralized with the carbonate of the metal whose salt is sought. The solution was filtered boiling hot and evaporated to crystallization. In a few cases the slight solubility of the salt has made it necessary to treat the solid residue once more with boiling water. The second method of making the salts is to treat the barium sulfonate with equal molecules of the sulfate of the metal whose salt is sought and evaporating to crystallization after filtering.

Nine salts have been prepared by these methods. In every case the

<sup>1</sup> Determined by Professor A. L. Haines.

salts have crystallized in radial systems when pure. In many cases the salts at first have crystallized in thin plates and arranged themselves in the radial form only after repeated crystallization. The solubilities of the salts show wide variation, but appear to follow certain regularities, depending upon their position in the periodic system. The analysis of the salts for the metal gives in every case results which are slightly too high. The results for nitrogen seem to be uniformly too low. If this is actually caused by occlusion, it seems strange that repeated crystallization does not change the percentage. The following tabulation shows how the salts were prepared, their crystal form, solubility and analysis:

TABLE II.

Name of salt.	Method of preparation.	Nature of crystals.	Solubility in 100 cc. at 20° C.	Analysis.	
				Found.	Theory.
Barium.....	Carbonate on sulfonic acid	Thin glistening plates	0.51	Ba	Ba
	Carbonate on sulfonic acid			Sr	Sr
Strontium.....	Carbonate on sulfonic acid	Friable warts	2.46	Ca	Ca
	Carbonate on sulfonic acid			N <sub>2</sub>	N <sub>2</sub>
Calcium.....	acid	Shiny scales	10.578	6.51	6.37
		Glistening white granules		N <sub>2</sub>	N <sub>2</sub>
Sodium.....	Both methods were used	Radial aggregations of thin plates	9.872	4.14	4.40
		Warty masses of thin scales		K	K
Potassium.....	Both methods were used	Thin plates	4.02	11.80	11.73
Copper.....	Decomposition of the barium salt	Large thin glistening plates	44.48	Cu	Cu
	Decomposition of the barium salt			9.85	9.74

Lead.....	Both methods were used	Hard, brownish warts	8.20	...	25.65
					N <sub>2</sub>
					1.69

All the salts were heated in an air bath first to 108° and then to 125° in an attempt to determine whether the salts contained water of crystallization or not. In only two cases did the loss seem to correspond to definite amounts of water of crystallization. The barium salt contained water equivalent to one-half molecule, and the copper salt an amount equalling exactly two molecules of water. The potassium salt lost no water at all on heating. The copper and the silver salts are both difficult to isolate in pure form, the former because of its extreme solubility, which made final evaporation in a vacuum desiccator necessary, and the latter because of its unusual sensitiveness to light. It was finally prepared in the dark by removing the water *in vacuo*. When so prepared it is of glistening whiteness, but it darkens somewhat even when kept in a deep red bottle. The crystals are slippery to the touch, some-

what like boric acid. The copper, silver, cadmium and lead salts are readily darkened by traces of hydrogen sulfide in the air, the lead salt being unusually sensitive. Practically every one of the salts darkens on exposure to the light and air, the sodium and potassium salts being the least affected.

***o*-Nitrophenyl Ether Sulfonyl Chloride.**—The sulfonyl chloride of nitrophenyl ether was prepared by taking 2 g. of ortho nitrophenyl ether sodium sulfonate, powdering, and thoroughly mixing in a mortar with 4 g. of powdered phosphorus pentachloride. As no action took place at once, it was heated on a steam bath for some minutes when the color became darker and the whole assumed a waxy appearance. The reaction product was then added to ice water in a flask and shaken for some minutes, when the oil that first separated crystallized out. The sulfonyl chloride was separated from the water by filtration with suction. It was in the form of round granules. These are insoluble in water, but soluble in hot alcohol from which they crystallized on standing into beautiful, needle-like, white crystals.

***o*-Aminophenyl Ether Hydrochloride.**—It is not easy to reduce ortho nitrophenyl ether to the corresponding amino compound by the ordinary methods, although if the alcoholic solution is boiled with tin and hydrochloric acid for eight hours, using a reflux, the reduction may be brought about. Complete reduction is determined by complete solution. As soon, therefore, as a few drops of the solution when removed and added to a large volume of water failed to leave behind an insoluble oil, the action was judged to be complete. The ether is best reduced, however, by the stannous chloride method first suggested by Ullmann.<sup>1</sup> By evaporating the menstruum long needle crystals of the tin salt separate out. These are dissolved in water which is slightly acid with hydrochloric acid and the tin completely removed by means of hydrogen sulfide. The filtrate must not be heated in contact with the air for the compound is easily oxidized. The water is therefore distilled off to small volume *in vacuo*. The crystals separate in large scales melting with decomposition at 154°. The free base may be liberated from the hydrochloride by treatment with ammonia. The crude oily mass left when the ether is evaporated is crystallized from xylene, giving crystals that decompose at 43 to 45° and darken on standing.

**The Unsulfonated Diazo Dyes.**—In the preparation of these dyes, the solution of the ortho amino hydrochloride was prepared by boiling the ether with stannous chloride for an hour, or all night with tin and hydrochloric acid as has already been described. After the solution has been de-tinned by hydrogen sulfide, filtered and boiled for some time to remove all traces of the gas, the solution has a distinct and characteristic

<sup>1</sup> *Ber.*, 29, 1878 (1896).

odor resembling that of garlic. A weighed amount of ether having been taken, the solution was made up of such strength that each cubic centimeter contains one-tenth gram of the amino hydrochloride. In like manner the solution of the compound with which the diazotized body is coupled was made of known strength. In this way it was easy to mix correct molecular proportions by measuring the volumes. The *o*-aminophenyl ether hydrochloride solution was cooled with ice to 5° and diazotized with a cold solution of sodium nitrite. Upon evaporation the diazonium salt crystallizes for the most part in round, crystalline balls of reddish brown color. The crystals burn readily but do not explode when heated. Solutions containing equal molecules of the diazotized salt of *o*-aminophenyl ether and the substance to be coupled with it are mixed in the cold and boiled. The dyeing was done upon white nuns-veiling which had been mordanted with dilute tartar emetic solution. The dry dye was obtained in each case and crystallized from alcohol. Most of the dyes decompose when a melting point is attempted. While few of the dyes possess shades which might render them of commercial value in spite of the high cost, the opportunity for comparisons of shade which the preparation of the sulfonated and unsulfonated dyes of both the ortho and para series offers, makes their preparation and study of value. The value of this comparison is increased by the fact that the dye solution in every case is of exactly the same concentration, so that shades are strictly comparable. The abbreviations used in the following table are those employed in the Milton Bradley Color Standard supplied with Mulliken's "Identification of Pure Organic Compounds." It is impossible to give an accurate idea of the exact tone of the color without the dyed samples for comparison, and yet this Color Standard makes at least an approach to this possible. All the dyes of this series have been tested thoroughly for light and wash-fastness and in no case has one of them faded.

**The *o*-Aminophenyl Ether Dyes—Sulfonated Series.**—In the preparation of these dyes *o*-nitrophenyl ether potassium sulfonate was reduced with tin and hydrochloric acid. It is noticed that the introduction of the sulfonic acid radical makes the reduction of the nitro group much easier. The reduction is accomplished in this case within a half hour by using tin and hydrochloric acid and heating over a water bath. It is not possible, however, to determine the point of complete reduction in this case so easily as with the unsulfonated ether because the compounds before and after the reduction are both soluble. When reduction is complete, which is best told by a change of color, the solution is de-tinned and diazotized. The diazotized solution was then coupled with the same eighteen reagents as before and a new series of sulfonated phenyl ether dyes obtained. The shades of the dye on wool as well as those of the dry dyes are shown in Table III. The dye obtained in this case with

dimethyl aniline hydrochloride is an unusually pleasing and brilliant bluish purple.

***p*-Nitrophenyl Ether.**—This compound was first made in 1896 by Haeussermann and Teichmann<sup>1</sup> by heating *p*-chloronitro benzene with potassium phenolate dissolved in phenol. It has been more recently made by Mailhe and Murat<sup>2</sup> by the nitration of phenyl ether. We first prepared the compound by the method described by Haeussermann and Teichmann and a very dark reaction product was obtained. On extraction with ether we got a dark-colored extract which on evaporation gave a mass of dark crystals. Recrystallizing once from alcohol, the melting point was 65°. Haeussermann and Teichmann gave 62°, Mailhe and Murat 56°. We next prepared the compound by heating *p*-bromonitrobenzene with potassium phenolate without a solvent for fourteen hours on a boiling water bath. In this process a large amount of sublimate gathered on the walls of the flask. These crystals were white, glistening and of long needle structure. They melted sharply at 123.5°. The reaction product was then distilled *in vacuo* boiling at 209° at 45 mm. The distillate on being recrystallized from alcohol melted at 118°. We questioned if the crystallized sublimate could be *p*-nitrophenyl ether. We, therefore, recrystallized the substance seven times with alcohol, and at last obtained a compound melting sharply at 123°. In our work we have obtained crystals melting all the way from 65° up. It seems certain, therefore, from these facts as well as from the analysis for nitrogen, which showed 12.21%, the theory being 12.3%, that the crystals obtained by sublimation were pure *p*-nitrophenyl ether, and that the true melting point of this compound is 123.5°. There is a marked difference between the stability of *o*- and *p*-nitrophenyl ether. The para compound may be distilled at ordinary pressure with little decomposition, the boiling point being 320°. It is insoluble in water, but slightly soluble in ligroin, but readily soluble in alcohol, ether, chloroform, benzene, acetone and other organic solvents.

***p*-Nitrophenyl Ether Sulfonic Acid.**—The free sulfonic acid of *o*-nitrophenyl ether is prepared with the greatest difficulty by the decomposition of the cadmium salt, while on the other hand, the corresponding acid of the para ether is prepared with the greatest ease. It is much more difficult to sulfonate *p*-nitrophenyl ether, however, fuming sulfuric acid (33%) being required, while concentrated sulfuric acid in the cold sulfonates the ortho ether. To 10 g. of *p*-nitrophenyl ether are added 40 g. of the fuming sulfuric acid. The whole is heated on a water bath for one hour, or until the ether has entirely gone into solution. The reaction product is now poured into 250 cc. of cold water with constant stirring. The free acid crystallizes out at once. It is most conveniently purified by recryst-

<sup>1</sup> *Ber.*, 29, 1446 (1896).

<sup>2</sup> *Compt. rend.*, 145, 715 (1912).

tallizing from hot water. The acid melts at  $132^{\circ}$ , and readily decomposes a soda solution. The crystals do not seem to be at all hygroscopic. An analysis of the acid for sulfur gave 10.79%, the theory being 10.85%.

**The Sulfonic Acid Salts.**—The sulfonic acid salts of *p*-nitrophenyl ether were prepared by neutralizing the acid with the carbonate of the metal, or by decomposing the barium salt with the sulfonate of the metal as in case of the salts of the ortho series. Because of the greater insolubility of the *p*-sulfonic acid and all its salts, a larger volume of water must be used, which should be boiling hot. The filtration by suction must be carried out rapidly and the precipitate thoroughly washed with boiling water. The para salts all have the same radial structure noted in the case of the ortho salts, but the crystals are better formed and larger. The para potassium sulfonate has one of the most beautiful crystal forms we have ever seen, crystallizing in concentric tufts as large as a pigeon's egg, and as delicate as a snow flake. The crystals are of glistening whiteness, and show little tendency to discolor on exposure to light and air. The following table shows the salts prepared, their crystal forms, solubilities, etc.:

TABLE IV.

Name of salt.	Method of preparation.	Nature of crystals.	Solubility in 100 cc. at $20^{\circ}$ C.	Analysis.	
				Found.	Theory.
Barium.....	Carbonate on sulfonic acid	Small, glistening, white flakes	0.25	Ba	Ba

				25.65	25.65
Lead.....	Both methods were used	Brownish nodules	6.29	1.69	1.69

***p*-Aminophenyl Ether Hydrochloride.**—*p*-Nitrophenyl ether is much more easily reduced to the amino compound than is the corresponding ortho ether. The ether is dissolved in alcohol and boiled with tin and hydrochloric acid on a water bath for an hour or until an oil is no longer obtained, when a few drops of the substance are transferred to water. The alcohol is now evaporated and if necessary water added to keep the solu-

tion clear. The whole is de-tinned with hydrogen sulfide, filtered and the water evaporated *in vacuo*. When small volume has been reached, the hydrochloride crystallizes out in the distilling flask. The crystals are thin, irregular-shaped plates of glistening whiteness. They are perfectly stable either wet or dry and melt at  $122^{\circ}$ . The salt on analysis gave 16.34% chlorine, the theory being 16.03%.

The hydrochloride in water solution was neutralized with ammonia, which liberated the free amine as an oil. This was extracted with ether and recrystallized from alcohol. It melts at  $95^{\circ}$ . Haeussermann and Teichmann<sup>1</sup> give the melting point as  $84^{\circ}$ . Nollau and Daniels<sup>2</sup> give the melting point as  $33^{\circ}$  to  $34^{\circ}$ . Their product was undoubtedly impure. The body is stable in the air and can be distilled undecomposed. On treatment with chloroplatinic acid the amine gives a chloroplatinate which crystallizes in long reddish brown needles.

**The *p*-Aminophenyl Ether Dyes.**—The amino hydrochloride was diazotized and coupled with various reagents. The same eighteen were used here as in the case of the ortho dyes and in just the same concentration. Nuns-veiling was dyed in each case and samples of the pure, dry dye obtained. The para dyes are much more stable, less soluble and better crystalline than the ortho dyes. Most of them can be obtained in pure form by crystallization in alcohol. Several of these melt sharply and without decomposition. Most of the dyes decompose somewhat, however, as they melt. While the shades obtained with these para dyes are in a few cases not so brilliant as the corresponding ortho dyes, the fact that *p*-nitrophenyl ether is so much more easily and cheaply prepared and also more easily reduced to the amino compound would tend to make them at least commercially of much greater importance. There is also the added fact that the *p*-aminohydrochloride is perfectly stable both when in solution and when dry, whereas the ortho compound must not be heated when exposed to the air. The four dyes made by coupling the diazotized amine with meta phenylene diamine, dimethyl aniline hydrochloride,  $\beta$ -naphthyl amine, gamma disulfonic acid and  $\alpha$ -naphthol, might easily become of commercial importance. Table V is exactly similar to the tables of the ortho dyes. The dye concentration and the color notation are the same as in the preceding tables.

**The *p*-Aminophenyl Ether Dyes — Sulfonated Series.**—*p*-Nitrophenyl ether potassium sulfonate is used as the basis of these dyes. It is reduced with tin and hydrochloric as before and the reduction is accomplished very easily and in short time. The solution of the sulfonated amino hydrochloride, after being de-tinned and filtered, is diazotized with sodium nitrite solution and coupled with the same eighteen reagents as

<sup>1</sup> *Ber.*, 29, 1446 (1906).

before. The same concentrations are used. The presence of the sulfonic acid group renders the dyes more soluble, less intense and harder to isolate in the crystal form. The para sulfonated dyes differ from the others prepared in being explosive when heated. Indeed many of the sulfonic acid salts of *p*-nitrophenyl ether are very explosive. Table V of sulfonated dyes obtained from *p*-aminophenyl ether is exactly comparable with the other tables and furnishes opportunity for the accurate study of the variation in shade produced by varying the position of the diazonium group and the introduction of the potassium sulfonate group.

### Summary.

1. A new method has been devised for preparing potassium phenolate applicable to all non-nitrophenols.
2. The properties of *o*- and *p*-nitrophenyl ethers have been more fully determined and numerous errors corrected.
3. Eighteen new sulfonic acid salts of *o*- and *p*-nitrophenyl ether have been prepared and studied.
4. Seventy-two diazo dyes have been made and studied. These were equally distributed between the sulfonated and unsulfonated series of both the ortho and para ethers.
5. The effects of the positions of the groups upon the properties of the compounds and the colors of the dyes have been carefully studied and the following points have been observed:
  - a. *o*-Nitrophenyl ether and all its compounds are more soluble than the corresponding para bodies and do not crystallize so well.
  - b. *p*-Nitrophenyl ether and all its derivatives are more stable than the corresponding ortho compounds. This is especially noticeable in the case of the amino hydrochloride and the free sulfonic acid.
  - c. *o*-Nitrophenyl ether is more easily sulfonated, harder to reduce and its amino body is easier to diazotize than the para body.
  - d. The *o*-aminophenyl ether dyes tend mostly to the reds and browns, though a few purple and yellow dyes have been produced.
  - e. The ortho dyes are more brilliant than the para.
  - f. The sulfonated dyes are more soluble and less brilliant than the unsulfonated.

### CHRONOLOGICAL BIBLIOGRAPHY OF THE PHENYL ETHERS.

1. 1845 Ettling and Stenhouse, *Ann.*, 53, 77 and 91.  
First subjected copper benzoate to destructive distillation.
2. 1855 List and Limpricht, *Ann.*, 90, 209.  
Obtained diphenyl ether from the destructive distillation of copper benzoate and called it "phenyl oxide."
3. 1862 Fittig, *Ann.*, 125, 328.  
Obtained diphenyl ether in the same way and separated diphenyl from it by treatment with sulfuric acid.

4. 1866 Lesimple, *Ann.*, 138, 375.  
Obtained a substance which he erroneously considered phenyl oxide by distilling phenyl phosphate with lime.
5. 1870 Clemm, *J. prakt. Chem.*, 1, 161.  
Attempted to prepare trinitrophenyl ether from picryl chloride and sodium phenolate in alcoholic solution, but failed.
6. 1871 Hoffmeister, *Ann.*, 159, 191, and *Ber.*, 3, 747 (24, 123).  
Prepared phenyl ether by treating diazobenzene sulfate with phenol. Carefully studied the compound and settled questions that had been in dispute.
7. 1873 Maikopar (article by Wredon), *Ber.*, 6, 564 (26, 1026).  
First manufactured a nitrophenyl ether by treating a nitro halogen benzene with an alkaline phenolate in alcoholic solution.
8. 1879 Willgerodt, *Ber.*, 12, 762 (36, 716).  
Made a dinitrophenyl ether by using dinitrochlorobenzene and potassium phenolate in carbon bisulfide solution. Probably same compound as in (7).
9. 1879 Willgerodt, *Ber.*, 12, 1277 (36, 923).  
Made a trinitrophenyl ether from picryl chloride using phenol, alcohol and water as a menstruum.
10. 1880 Willgerodt, *Ber.*, 13, 887 (38, 642).  
Made a tetranitrophenyl ether by heating dinitro potassium phenolate and dinitrochlorobenzene in sealed tubes.
11. 1881 Merz and Weith, *Ber.*, 14, 187 (40, 264).  
Prepared phenyl ether by heating phenol with zinc chloride at 350°; yield, 5%; and also by heating phenol with aluminum chloride; yield, 10 to 12%. (See also *Ber.*, 12, 1925.)
12. 1882 Boehmer, *J. prakt. Chem.*, 24, 449; also *Ber.*, 15, 83 (42, 1, 396).  
Made phenol bromophenyl ether by the action of hydrobromic acid on diazophenol nitrate or sulfate.
13. 1882 Niederhaeusern, *Ber.*, 15, 1119 (42, 1, 1211).  
Prepared diphenyl ether by heating sodium phenolate with sodium metaphosphate and obtained methylene diphenyl oxide as a by-product.
14. 1882 Richter, *J. prakt. Chem.*, [2] 23, 349 (42, 1, 618).  
Distilled phenyl phosphate with sodium salicylate and obtained oxydiphenyl ketone which on reduction yielded phenyl ether.
15. 1882 Gladstone and Tribe, *J. Chem. Soc.*, 41, 5.  
Made aluminum phenolate, cresolate and thymolate and distilled these obtaining phenyl ether and some of its derivatives.
16. 1883 Klepl, *J. prakt. Chem.*, [2] 28, 201 (46, 1, 446).  
Prepared *p*-phenoxy benzoic acid by passing carbonic anhydride over *p*-hydroxy benzide. He obtained phenyl ether by distilling *p*-phenoxy benzoic acid with baryta.
17. 1884 Richter, *J. prakt. Chem.*, [2] 23, 293 (46, 1, 324).  
Obtained phenyl ether by distilling phenyl phosphate and sodium salicylate.
18. 1884 Willgerodt and Huetlin, *Ber.*, 17, 1764 (46, 1, 1328).  
Prepared four nitrophenyl ethers by treating di- and trinitrochlorobenzenes with potassium *o*- and *p*-nitrophenolates in alcoholic solution.
19. 1884 Buch, *Ber.*, 17, 2638 (48, 1, 147).  
Made ditolyl ether as a by-product of heating *p*-cresol with zinc chloride.

\* The numbers in parenthesis refer to the location of the abstract in the Abstract Volume of *The Journal of the London Chemical Society*.

20. 1886 Gladstone and Tribe, *J. Chem. Soc.*, **49**, 25.  
Made *m*- and *p*-cresyl ethers by the dry distillation of aluminum cresolates.
21. 1888 Graebe, *Ber.*, **21**, 501 (54, 1, 447).  
Prepared *o*-phenoxy benzoic acid.
22. 1890 Hirsch, *Ber.*, **23**, 3705 (60, 1, 437).  
Decomposed diazobenzene with phenol; yield, 50% of the weight of the aniline used.
23. 1896 Haeussermann and Teichmann, *Ber.*, **29**, 1446 (70, 1, 533).  
Made several nitrophenyl ethers and their derivatives by heating the chloro-nitro benzenes with potassium phenolate and phenol.
24. 1896 Ullmann, *Ber.*, **29**, 1878 (70, 1, 605).  
Makes *o*-nitro- and aminophenyl ethers.
25. 1896 Haeussermann and Bauer, *Ber.*, **29**, 2083 (70, 1, 676).  
Continued the work of Haeussermann and Teichmann using the same methods.
26. 1896 Jeitles, *Monatsh.*, **17**, 65 (70, 1, 434).  
Obtained a diphenyl ether by the distillation of calcium *o*-phenoxy benzoate.
27. 1897 Haeussermann and Bauer, *Ber.*, **30**, 738 (72, 1, 333).  
Continued their former work and prepared numerous compounds.
28. 1898 Peratoner and Ortoleva, *Ital. Gazzetta*, **28**, [1] 197 (74, 1, 643).  
Obtained chlorine derivatives of phenyl ether by treating with sulfonyl chloride.
29. 1900 Cook and Hillyer, *Am. Chem. J.*, **24**, 525 (80, 1, 144).  
Prepared 2-nitro-4'-methylphenyl ether and several derivatives.
30. 1901 Cook and Frary, *Am. Chem. J.*, **28**, 486 (84, 1, 163).  
Prepared 4-nitro-3'-methylphenyl ether and several derivatives.
31. 1901 Haeussermann and Schmidt, *Ber.*, **34**, 376 (82, 1, 126).  
Prepared azoxyphenyl ether by electrolytic reduction of the nitro compound and the corresponding amino compound by using the tin cathode.
32. 1901 Cook, *THIS JOURNAL*, **23**, 806 (82, 1, 92).  
Prepared 2-nitro-2'-methylphenyl ether and 2-nitro-3'-methylphenyl ether and several derivatives.
33. 1902 Cook and Eberly, *THIS JOURNAL*, **24**, 1200 (84, 1, 250).  
Prepared 4-nitro-2'-methylphenyl ether and several derivatives.
34. 1903 Cook, *THIS JOURNAL*, **25**, 60 (84, 1, 337).  
Prepared 4-nitro-4'-methylphenyl ether and several of its derivatives.
35. 1904 Cook, *THIS JOURNAL*, **26**, 302 (86, 1, 400).  
Describes the properties of phenyl ether.
36. 1904 Ullmann, *Ber.*, **37**, 853 (86, 1, 417).  
Made phenoxy benzoic acid using copper as a catalyst.
37. 1905 Ullmann and Sponagel, *Ber.*, **38**, 2311 (88, 1, 644).  
Made phenyl ether using copper as a catalyst and increased the yield from 0.9% to 87%.
38. 1905 Cook, *THIS JOURNAL*, **28**, 608 (90, 1, 495).  
Studied aluminum phenolate and its use in the preparation of phenyl ether.
39. 1905 Reverdin and Dressel, *Ber.*, **38**, 1593 (88, 1, 51).  
Prepared some new nitrophenyl ethers.
40. 1905 Kipper, *Ber.*, **38**, 2490 (88, 1, 648).  
A study of the Friedel and Crafts reaction on phenyl ether.
41. 1906 Cook, *Am. Chem. J.*, **36**, 543 (92, 1, 126).  
The distillation of aluminum *m*-cresolate; the preparation of *m*-tolyl ether and its derivatives.

42. 1906 Ullmann and Sponagel, *Ann.*, **350**, 84 (92, 1, 38).  
A study of the yields obtained with various halogen benzene and alkaline phenolates in the presence of finely divided copper.
43. 1906 Ullmann and Stein, *Ber.*, **39**, 622 (90, 1, 258).  
Made various methoxy and hydroxy phenyl ethers.
44. 1910 Cook, *THIS JOURNAL*, **32**, 1285 (98, 1, 731).  
A study of the bromination of phenyl and tolyl ethers.
45. 1910 Sabatier and Mailhe, *Compt. rend.*, **151**, 492 (98, 1, 669).  
Manufactured phenyl ether and its homologs by the use of thorium oxide as a catalytic agent.
46. 1910 Bonneaud, *Bull. soc. chim.*, [IV] **7**, 776 (98, 1, 669).  
A study of the action of bromine in the presence of aluminum bromide, on the phenyl ethers and their homologs.
47. 1910 Farb. v. Friedr. Bayer & Co. (98, 1, 312, 373).  
A description of the preparation of dyes from some diazotized aromatic amino ethers.
48. 1911 Cook, *THIS JOURNAL*, **33**, 254.  
An addenda to No. (44) containing omitted material.
49. 1911 Borsche and Rautscheff, *Ann.*, **379**, 152 (100, 1, 329).  
A study of the reaction of chloronitro benzene in which they prepared 2:6-dinitrophenyl ether.
50. 1912 Mailhe and Murat, *Bull. soc. chim.*, **154**, 122-3 (1912, 1-183).  
Made a study of the decomposition of phenyl ether by hydrogen in the presence of heated nickel.
51. 1912 Mailhe and Murat, *Compt. rend.*, **154**, 601 and *Bull. soc. chim.*, [IV] **11**, 288 (102, 1, 254).  
A study of the halogen derivatives of phenyl and ditolyl ethers.
52. 1912 Mailhe and Murat, *Compt. rend.*, **154**, 715 (102, 1, 346).  
A study of the nitration of phenyl ether.
53. 1912 Mailhe, *Compt. rend.*, **154**, 1240 (102, 1, 548).  
A description of the dyes obtained by treating diazotized *p*-amino phenyl ether with various compounds.
54. 1912 Sabatier and Mailhe, *Compt. rend.*, **155**, 260 (102, 1, 767).  
An extension of previous studies, several new compounds being produced.
55. 1914 Nollau and Daniels, *THIS JOURNAL*, **36**, 1885 (106, 1, 1129).  
A study of the reaction of the alkaline salts of sulfonic acids with the alkaline phenolates resulting in the preparation of various aromatic ethers.
56. 1915 Cook and Sherwood, *THIS JOURNAL*, **37**, 1835 (108, 1, 877).  
Made a number of new derivatives of phenyl ether.

MITCHELL, S. DAKOTA.

CO— are characterized by their behavior towards potassium thiocyanate. They interact with this salt with formation of normal thiocyanates, and in no case, which has been carefully investigated, has it been demonstrated that mustard oils are products of the reaction. Furthermore, it has never been shown, so far as the writers are aware, that thiocyanates of the type  $\text{NCS.CH}_2\text{CO.R}$  can be rearranged by heat into the isomeric mustard oils  $\text{SCNCH}_2\text{CO.R}$ . Such transformations have been assumed to take place by different investigators and also the reverse change,  $\text{SCN.CH}_2\text{COR} \rightarrow \text{NCS.CH}_2\text{COR}$ , but a careful reëxamination of their work has been productive of evidence, in every case investigated, that such conclusions are incorrect. Changes of an entirely different nature have been observed to take place, and they do not involve a migration of the polyketide group  $\text{—CH}_2\text{CO.R}$  from sulfur to nitrogen of the SCN radical.<sup>1</sup>

Recent developments in this laboratory<sup>2</sup> have now directed our attention again to the chemistry of these polyketide mustard oils. In connection with our work on polypeptide-hydantoins we have foreseen the possibility of utilizing certain combinations of this type for coupling with  $\alpha$ -aminoacids and consequently it was necessary to have available a practical method whereby they can be obtained in quantity for synthetical purposes. Such a method of synthesis has now been developed and in this paper we shall give a description of its application for the preparation of ethyl isothiocyanacetate,  $\text{SCN.CH}_2\text{COOC}_2\text{H}_5$ . So far as we are aware, this is the first polyketide isothiocyanate (mustard oil) to be described in the literature whose constitution has been definitely established.

In 1890, P. Klason published an interesting paper entitled, "Ueber Senfölessigsäure und Thiohydantoin," in which he described the preparation of ethyl isothiocyanacetate. He states that it is formed by the action of thiophosgene or ethyl aminoacetate in ether solution and expressed the transformation by the following equation:

The reaction apparently was a smooth one and the ester was obtained in good yield, but from what we can learn from abstracts of his original publication nothing was done by him to establish its constitution. While the results of this work are recorded, to our knowledge, in three different journals,<sup>3</sup> the mustard oil is not listed in Richter's *Lexikon der Kohlenstoff Verbindungen* nor described in Beilstein's *Handbuch*. It was undoubtedly due to this omission that Wheeler, in 1901, was led to insert, in one

<sup>1</sup> See previous papers from this laboratory.

<sup>2</sup> Unpublished results.

<sup>3</sup> *Ofv. kongl. Vet.-a. .*, 87 (1890); *Chem. Ztg.*, 14, Rep. 200; *Chem. Zentr.*, 2, 344 (1890).

of his earlier papers on alkylthiocyanates,<sup>1</sup> the following statement: "The results, now at hand, show that neither isothiocyanacetic acid nor any of its derivatives have yet been prepared."

During this same year (1901), E. Fischer investigated the action of phosgene on ethyl aminoacetate and showed that they interact in toluene to form the urea (I).<sup>2</sup> Apparently he obtained no evidence of the formation of the isocyanate (II) corresponding to ethylisothiocyanacetate.

(I).

(II).

He did not take up the study of the action of thiophosgene on ethyl aminoacetate and furthermore makes no reference, in his paper, to the previous work of Klason. On the other hand, he attempted to convert the amino ester into ethyl isothiocyanacetate by combining it with carbon bisulfide and then breaking down the resulting dithiocarbamic acid salt (III) in the usual manner by digestion in aqueous solution with metallic salts. Fischer found that the salt (III) is formed smoothly, but the only evidence given in the paper indicating that an isothiocyanate was formed by its decomposition is the statement that the odor of mustard oil was apparent after digesting with mercury salts. Ethyl isothiocyanacetate was not isolated.

(III).

While ethyl aminoacetate interacts with phosgene to give the corresponding urea (I), the hydrochloride of this ester reacts with phosgene in an entirely different manner. Morel and Gautier<sup>3</sup> made the observation that they interact, when warmed in toluene, with evolution of hydrochloric acid and formation of the isocyanate (II). This reactive substance was obtained as an oil which could be distilled without decomposition, but was transformed by the action of water into the urea,  $\text{CO}(\text{NH}.\text{CH}_2\text{COOH})_2$ , originally obtained by Fischer.<sup>4</sup>

In the light of these developments it was of especial interest to investigate the behavior of thiophosgene towards the hydrochloride of ethyl aminoacetate. We now find that these substances interact at the temperature of boiling toluene giving Klason's ethyl isothiocyanacetate. In fact the yield is excellent and the ester can be synthesized in quantity without difficulty. We obtained no evidence of the formation of the thio-urea,  $\text{CS}(\text{NHCH}_2\text{COOC}_2\text{H}_5)_2$ . The reaction is expressed by the following equation:

<sup>1</sup> Wheeler and Merriam, *THIS JOURNAL*, 23, 183 (1901).

<sup>2</sup> *Ber.*, 34, 440 (1901).

<sup>3</sup> *Compt. rend.*, 143, 119 (1906).

<sup>4</sup> *Loc. cit.*

From this result it is apparent that the equation formulated by Klason<sup>1</sup> to express the behavior of thiophosgene towards ethyl aminoacetate applies only when one molecular proportion of thiophosgene is used. The incorporation of an excess of thiophosgene would lead to a complete transformation of the aminoacetate into the corresponding isothiocyanate. Under these conditions the reaction would conform to the following expression:

Ethyl isothiocyanacetate boils at practically the same temperature as ethyl thiocyanacetate without undergoing a molecular rearrangement. It exhibits the properties of a true mustard oil and interacts with amines giving thiourea combinations or thiohydantoates. For example, it interacts with aniline giving the same thiohydantoate as was obtained by Fischer<sup>1</sup> by the action of phenylisothiocyanate on ethylaminoacetate.

Especially interesting was the behavior of this ester towards anhydrous ammonia. The isomeric ethyl rhodan acetate reacts with this reagent to form the corresponding amide<sup>2</sup>— $\text{NSC} \cdot \text{CH}_2\text{CO} \cdot \text{NH}_2$ . When a benzene solution of the ethyl isothiocyanacetate was saturated with ammonia gas at ordinary temperature the corresponding thiohydantoate (IV) was not formed as expected, but the mustard oil was converted practically quantitatively into 2-thiohydantoin (VI). This is a new method of entering the hydantoin series and the ease with which the hydantoin is formed at such a low temperature suggests that the thiohydantoate (IV) is not an intermediate product of the reaction. Harries and Weiss<sup>3</sup> were unable to convert this hydantoate into 2-thiohydantoin by hydrolysis. Klason<sup>1</sup> accomplished the transformation by heating the hydantoate at 140–150°. Johnson<sup>4</sup> recently confirmed this observation of Klason's but showed that the reaction is of no practical importance for the preparation of the thiohydantoin. It is not improbable that the ethyl isothiocyanacetate interacts with ammonia in a similar manner as its isomer (ethyl thiocyanacetate) with formation of the amide (V). If such a combination were formed it would be expected to undergo an inner condensation with formation of the 2-thiohydantoin (VI). A substituted acid amide (VII) on condensation would lead to the forma-

tion 1-phenyl-2-thiohydantoin (VIII). It has been shown in a paper from this laboratory<sup>1</sup> that the corresponding anilides of rhodanacetic acid (IX) condense in an entirely different manner, giving pseudothiohydantoin combinations (X).

It is our intention to investigate the action of thiophosgene on other  $\alpha$ -aminoacids and to develop new reactions which will serve to distinguish polyketidethiocyanates (XI) from polyketideisothiocyanates (XII).

### Experimental Part.

**The Preparation of Thiophosgene,  $\text{CSCl}_2$ .**—All the thiophosgene used in our work was manufactured by reduction of tetrachloromethylmercaptan with stannous chloride according to the method of Kern and Sandoz.<sup>2</sup> The tetrachloromethylmercaptan was prepared by chlorination of carbon bisulfide.<sup>3</sup> We have prepared several thousand grams of this reagent this year, and have in progress several researches dealing with its application for synthetical purposes. The operation is carried on in the following manner: Five pounds of carbon bisulfide, to which is added about 5 g. of iodine as a catalyzer, are placed in a large bottle and cooled with ice-water. This bottle is connected with a condenser and the operation conducted in a hood. Chlorine gas from a bomb is then passed rapidly into the bisulfide until the increase in weight corresponds to 5 atomic

<sup>3</sup> P. Klason, *Ber.*, 20, 2376 (1887).

proportions of the halogen. The crude reaction product is then washed by pouring into a tall, cylindrical glass retort and allowing water to circulate through the oil from the bottom. By running a constant stream of cold water beneath the oil and allowing to rise through it the sulfur halides are slowly decomposed and the soluble material gradually carried away. The tetrachloromethylmercaptan is thus obtained as a heavy oil and can be tapped off and distilled with steam to remove the last traces of sulfur halides. This last operation was applied twice and the mercaptan derivative then heated at  $142^{\circ}$  in an oil bath to remove carbon tetrachloride. This crude tetrachloromethylmercaptan was then used for the preparation of thiophosgene. From 5 pounds of carbon bisulfide we obtained 4.5 pounds of the tetrachloride. In order to prepare thiophosgene, 1.5 pounds of this tetrachloride were reduced at a time when we obtained from the 4.5 pounds of mercaptan 2.33 pounds of thiophosgene, corresponding to 84% of a theoretical yield. This was then bottled and used as needed in our research.

**Preparation of the Hydrochloride of Ethyl Aminoacetate,  $\text{HCl} \cdot \text{NH}_2\text{-CH}_2\text{COOC}_2\text{H}_5$ .**—All the ester used was prepared by esterification of methyleneaminoacetonitrile according to the directions of Klages.<sup>1</sup> Since potassium cyanide was not available we utilized commercial sodium cyanide for the manufacture of the nitrile. The modified procedure was not productive of as good yields as those obtained by Klages when potassium cyanide was used. The sodium cyanide seemed to favor the formation of the lower melting modification of methyleneaminoacetonitrile (m.  $86\text{--}87^{\circ}$ ). From 6000 g. of commercial 40% formaldehyde we obtained 853 g. of methyleneaminoacetonitrile melting at  $127\text{--}128^{\circ}$  and 328 g. of the lower melting modification. By hydrolysis of the 853 g. of methyleneaminoacetonitrile with alcohol and hydrochloric acid we obtained 1004 g. of the hydrochloride of ethyl aminoacetate.

**The Action of Thiophosgene on the Hydrochloride of Ethyl Aminoacetate. The Formation of Ethyl Isothiocyanacetate,  $\text{SCN} \cdot \text{CH}_2\text{COOC}_2\text{H}_5$ .**—This mustard oil is formed by the action of thiophosgene on the hydrochloride in either benzene or toluene solution. The yield is about 20 per cent. of theory when benzene is used and 50–60% when toluene is employed. Four hundred and twenty-five grams of the hydrochloride of ethylaminoacetate suspended in 600 cc. of toluene were heated in an oil bath at  $110\text{--}115^{\circ}$ , and 405 g. of thiophosgene (slightly more than one molecular proportion) added in small quantities during the course of eight hours. This mixture was then boiled gently for about one day in order to complete the reaction. There was still unaltered hydrochloride present after this treatment. This was separated by filtration and dried in the

<sup>1</sup> *Ber.*, 36, 1507 (1903).

air. It weighed 68 g. This was suspended again in fresh toluene and heated with an excess of thiophosgene in order to convert it completely into the mustard oil. After the reaction was complete the toluene was removed by heating at  $100^{\circ}$  under diminished pressure, when the isothiocyanate was obtained as a dark-colored oil. This new mustard oil was purified by distillation under diminished pressure. It boiled at  $112-113^{\circ}$  at 12 mm. and the yield corresponded to 60% of theory. In two other experiments our product boiled at  $110^{\circ}$  at 10 mm. and  $113^{\circ}$  at 15 mm. From 874 g. of the hydrochloride and 2.3 pounds of thiophosgene we obtained in all 642 g. of pure distilled isothiocyanate. This is a yield of 70% of the theoretical calculating from the weight of the hydrochloride used. In other words, from 5 pounds of carbon bisulfide, 11.6 pounds of chlorine and 6000 g. of 40% formaldehyde were produced 642 g. of mustard oil. This oil is colorless when first distilled, but turns red on standing. Under atmospheric pressure it boils at  $215^{\circ}$  with partial decomposition. Its density is 1.1710 at  $20^{\circ}$  (Westphal) and its refractive index is  $n_D^{20} = 1.5038$  (Abbe) and 1.5028 (Pulfrich).

**The Action of Ammonia on Ethyl Isothiocyanacetate. The Formation of 2-Thiohydantoin.**—Five grams of ethyl isothiocyanacetate were dissolved in 50 cc. of benzene and dry ammonia gas passed through the solution for one hour. There was an immediate reaction and during the operation a crystalline product separated from the benzene. This was identified as 2-thiohydantoin. It was purified by crystallization from alcohol and melted at  $227^{\circ}$  with decomposition. To further establish its identity it was mixed with 2-thiohydantoin prepared according to the method described by Johnson and Nicolet<sup>1</sup> and a melting point taken. The mixture and the pure hydantoin melted at exactly the same temperature.

#### Behavior of Ethyl Isothiocyanacetate towards Aromatic Amides.

**Action of Aniline: Ethyl 1-Phenylthiohydantoate,  $C_6H_5.NH.CS.NH.CH_2COOC_2H_5$ .**—Two and two-tenths grams of ethyl isothiocyanacetate and 1.4 grams of aniline were dissolved in 60 cc. of ether and the mixture digested on the water bath for several hours. On allowing the ether to evaporate spontaneously the above hydantoate was obtained in a crystalline condition. It crystallized from ether in the form of plates and melted at  $89^{\circ}$  to an oil. Fischer<sup>2</sup> prepared this same compound by the action of phenylisothiocyanate on ethyl aminoacetate and assigned to it a melting point of  $85^{\circ}$ .

Calc. for  $C_{11}H_{14}O_2N_2S$ : N, 11.74%. Found: N, 11.58, 11.51.

**Ethyl *p*-Tolylthiohydantoate,  $CH_3C_6H_4NHCSNHCH_2COOC_2H_5$ .**—This

<sup>2</sup> *Loc. cit.*

was easily obtained by action of *p*-toluidine on ethyl isothiocyanacetate. It was purified by crystallization from ether and alcohol and separated in long needles which melted at 96°. The hydantoate is soluble in benzene, ether and alcohol and insoluble in water.

Calc. for  $C_{12}H_{16}O_2N_2S$ : N, 11.13%. Found: N, 11.01, 10.96.

**Ethyl *o*-Tolylthiohydantoate**,  $CH_3C_6H_4NHCSNHCH_2COOC_2H_5$ .—From *o*-toluidine and ethyl isothiocyanacetate. The compound is soluble in alcohol and ether and insoluble in water. It melts at 90°.

Calc. for  $C_{12}H_{16}O_2N_2S$ : N, 11.13%. Found: N, 11.00, 10.97.

**Ethyl *m*-Tolylthiohydantoate**,  $CH_3C_6H_4NHCSNHCH_2COOC_2H_5$ .—From *m*-toluidine and ethyl isothiocyanacetate. It crystallizes from alcohol or ether in the form of prismatic needles and melts at 97°.

Calc. for  $C_{12}H_{16}O_2N_2S$ : N, 11.13%. Found: N, 11.25, 11.21.

**Ethyl *p*-Nitrophenylthiohydantoate**,  $NO_2.C_6H_4NHCSNHCH_2COOC_2H_5$ .—This ester crystallizes from alcohol in the form of light yellow needles arranged in rosetts. It melts at 191.5°.

Calc. for  $C_{11}H_{13}O_4N_3S$ : N, 14.87%. Found: N, 14.82, 15.00.

**The Action of Thiophosgene on the Hydrochloride of Glycocoll**.—Twenty grams of the hydrochloride of glycocoll were suspended in 60 cc. of toluene and 22 g. of thiophosgene added to the toluene. The mixture was then digested for two days at 110–115°. The unaltered hydrochloride was then separated by filtration and dried. Practically the whole amount taken was recovered unaltered.

NEW HAVEN, CONN.

[CONTRIBUTIONS FROM THE SHEFFIELD CHEMICAL LABORATORY OF YALE UNIVERSITY.]

## RESEARCHES ON PYRIMIDINES. LXXX. THE MECHANISM OF THE ACTION OF BROMINE ON 2-MERCAPTOPYRIMIDINES.

By TREAT B. JOHNSON AND A. WILLARD JOYCE.

Received June 17, 1916.

It is known that 6-oxypyrimidines of the three types represented by uracil (I), 2-methylmercapto-6-oxypyrimidine (II), and isocytosine or 2-amino-6-oxypyrimidine (III), interact, respectively, with chlorine, bromine and iodine with substitution of one hydrogen atom of the pyrimidine ring by halogen. Wheeler and Bristol<sup>1</sup> showed that the 5-position of the pyrimidine ring is the point of attack in such reactions leading to the formation of the corresponding 5-halogenated pyrimidines (VII, VIII and IX). These transformations, when bromine is used, are represented by the following formulas:

<sup>1</sup> *Am. Chem. J.*, **33**, 437 (1905); Johnson and Johns, *Ibid.*, **34**, 175 (1905); *J. Biol. Chem.*, **1**, 305 (1905).

When the 5-position of the ring in these series is occupied by an alkyl group ( $\text{CH}_3^-$ ,  $\text{C}_2\text{H}_5^-$ , etc.) and the 4-position is unsubstituted as, for example, in the case of thymine (X), the pyrimidine shows no tendency to interact with halogens, under normal conditions, with formation of halogen derivatives substituted in the 4-position (XI), or even in the side chain (XII), as is observed to take place with the higher homologs of benzene. The behavior of thymine towards halogens at high temperatures has not been investigated.

All these transformations very probably involve primarily an addition of bromine to the double bond of the pyrimidine ring giving unstable combinations (IV, V and VI), which then break down with formation of hydrobromic acid and 5-bromopyrimidines. In no case, however, has a halogen addition product of this type been isolated in these series. On the other hand, it has been shown that 2,6-dioxypyrimidines (thymine) readily combine with hypochlorous, hypobromous and even nitric acid giving stable addition products. For example, 5-bromouracil (XIII) and 5-nitouracil (XV) interact with concentrated nitric acid and hypobromous acid, respectively, giving the same hexahydropyrimidine (XIV).<sup>1</sup>

<sup>1</sup> Johnson, *Am. Chem. J.*, 40, 19, (1908).

Our knowledge of the action of halogens on 2-oxypyrimidines (XX), is very limited while the behavior of these elements towards the corresponding 2-mercaptopyrimidines (XXIII) has never been investigated. Evans<sup>1</sup> was the first to investigate the action of halogens on 2-oxypyrimidines and showed that 2-oxy-4,6-dimethylpyrimidine (XX) interacts with bromine water, giving a hexahydropyrimidine to which he assigned the constitution (XVI). This reaction was later reinvestigated by Stark<sup>2</sup> who made the interesting observation that this ketopyrimidine (XX) readily adds bromine in chloroform, forming an addition product which is unstable in the presence of water and alcohol. He assigned to this addition product the constitution XVII, and represented the products formed by treatment with water and alcohol according to Formulas XVIII and XIX. In other words, this pyrimidine, which is both acidic and basic in character and consequently can react in a tautomeric manner, adds bromine to the unsaturated group  $-\text{N} = \text{C}.\text{CH}_3$  instead of the ethylene group-

ing in positions 4 and 5 of the ring, as represented in the two tautomers of 2-oxy-4,6-dimethylpyrimidine (XXI) and (XXII).

In the light of these results it was of great interest to investigate the action of bromine towards 2-mercaptopyrimidines as represented by the general Formula XXIII. Compounds of this type are basic in character and cannot react in a tautomeric manner. In other words, they

<sup>1</sup> *J. prakt. Chem.*, 48, 489 (1893).

<sup>2</sup> *Ber.*, 42, 708 (1909).

do not contain a mobile hydrogen atom and consequently can be assigned only one constitution. This corresponds with that represented by the tautomeric formula of 2-oxy-4,6-dimethylpyrimidine (XXII).

We have now investigated the action of bromine on 2-methylmercaptopyrimidine and 2-ethylmercaptopyrimidine<sup>1</sup> (XXV). These two mercapto bases were prepared by reduction of their corresponding 2-mercapto-6-chloropyrimidines (XXIV). We find that both these pyrimidines add bromine quantitatively in carbon tetrachloride solution, forming addition products (XXVI) insoluble in this solvent. The 2-methylmercapto compound is a solid while its higher homolog was always obtained as a dark colored oil. In other words, the transformation of 2-mercapto-6-oxyprymidines into 2-mercaptopyrimidines is productive of greater unsaturation within the molecule, and the valency-force of the unsaturated ethylene grouping between positions 4 and 5 is greatly increased.

These addition products are the first representatives of a new class of dihydropyrimidines and are characterized by very unique properties. They easily undergo dissociation when warmed with water or dilute alkali, with regeneration of the original mercaptopyrimidines. This same change is also brought about quantitatively by the action of acetone. Both of the dihydropyrimidines (XXVI) interacted with this ketone at ordinary temperature with formation of bromoacetone and the hydrobromic acid salt of the original mercaptopyrimidines.

(R = CH<sub>3</sub> — and C<sub>2</sub>H<sub>5</sub> —.)

<sup>1</sup> Johnson and Joyce, *THIS JOURNAL*, 37, 2151 (1915).

These changes are perfectly analogous to those which have been observed to take place with similar combinations in the acyclic series. For example, Erlenmeyer and Muller<sup>1</sup> observed that  $\alpha,\beta$ -dibromobutyric acid (XXXII) easily loses bromine when warmed in aqueous solution with potassium iodide with formation of crotonic acid (XXXIII) and iodine.

(XXXII).

(XXXIII).

Especially interesting in this connection are observations of Pfeiffer<sup>2</sup> on the behavior of the asymmetric isomers or dibromostilbene and related compounds towards pyridine. While the  $\beta$ -modifications of dibromostilbene, (XXXV) and  $\beta$ -dinitrodibromostilbene (XXXVIII) interact with this reagent, on warming, to give the corresponding unsaturated monohalides represented by Formulas XXXVI and XXXIX, the  $\alpha$ -modifications, on the other hand, behave in an entirely different manner. They undergo dissociation in presence of the same reagent with formation of stilbene (XXXIV) and dinitrostilbene (XXXVII), respectively. These changes may be represented as follows:

(XXXIV).

(XXXV).

(XXXVI).

(XXXVII).

(XXXVIII).

(XXXIX).

So far as the writers are aware the behavior of such combinations towards acetone has never been investigated.

When the addition products (XXVI) are heated under pressure, hydrobromic acid is evolved and halogenated mercaptopyrimidine (XXIX) is obtained containing bromine in position 5 of the pyrimidine ring. The structure of the bromine derivative (XXXI), which was obtained by heating its corresponding methylmercapto addition product (XXVI), was established as follows: 2-methylmercapto-6-oxypyrimidine<sup>3</sup> (XXVII) was prepared and combined with bromine, when the bromopyrimidine (XXVIII) was easily formed. This was then converted into the pyrimidine (XXX) by interaction with phosphorus oxychloride. When this bromochloropyrimidine was reduced with zinc dust, the chlorine atom only was replaced by hydrogen and 2-methylmercapto-5-bromopyrimidine (XXXI) was obtained. This was identical with the bromopyrimidine

<sup>1</sup> *Ber.*, **15**, 49 (1882).

<sup>2</sup> *Ibid.*, **45**, 1810 (1912); **48**, 1048 (1915).

<sup>3</sup> Wheeler and Merriam, *Am. Chem. J.*, **29**, 478 (1903).

formed by heating the methylmercapto addition product (XXVI). Therefore *when 2-mercaptopyrimidines interact with bromine they form addition products, which break down on heating with substitution of the halogen in the 5-position of the pyrimidine ring.*

### Experimental Part.

**The Behavior of Bromine towards 2-Methylmercaptopyrimidine in Carbon Tetrachloride Solution: 2-Methylmercapto-4,5-dibromodihydropyrimidine (XXVI).**—The 2-methylmercaptopyrimidine used in this preparation was obtained by the reduction of 2-methylmercapto-6-chloropyrimidine.<sup>1</sup> Two grams of the 2-mercaptopyrimidine were dissolved in 20 cc. of carbon tetrachloride and the solution cooled with ice-water. To this were then added 3.5 grams of bromine dissolved in 20 cc. of cold carbon tetrachloride. The bromine which was used here was previously dried by washing with concentrated sulfuric acid. On mixing the above reagents a turbidity was produced and after standing a short time clusters of red needles deposited on the sides of the flask. After standing about 15 minutes, when the reaction was apparently complete, these crystals of the addition product were filtered off quickly by suction, washed with carbon tetrachloride and finally dried over concentrated sulfuric acid in a vacuum desiccator. The crystals could not be exposed to the air for any prolonged time, the substance being decomposed by moisture. We obtained 3.75 g. of the addition product while a theoretical yield would be 4.15 g.

This pyrimidine is very unstable in the presence of moisture and even on warming in anhydrous solvents, so that we were not able to purify it by crystallization. It is insoluble in carbon tetrachloride, benzene and ether. It is decomposed by water, alkalis and acids, with formation of the original 2-mercaptopyrimidine. We were not able to assign a sharp melting point to the compound. It began to melt, when heated in a capillary tube, at 65°, giving finally a clear oil at 75°.

Calc. for  $C_5H_6N_2SBr_2$ : N, 9.79%. Found: N, 9.53, 9.58.

**The Action of Acetone on the Addition Product.**—The dihydropyrimidine interacts with acetone at ordinary temperature. When treated with this reagent the addition compound dissolves, giving a yellow solution which becomes colorless on stirring and finally deposits the original 2-methylmercaptopyrimidine in the form of its hydrobromic acid salt. At the same time bromoacetone is formed which is easily recognized by its odor and irritating action on the eyes. The hydrobromide of the pyrimidine base was purified by crystallization from absolute alcohol and melted at 188° with decomposition.

Calc. for  $C_5H_6N_2S \cdot HBr$ : N, 13.52%. Found: N, 13.7.

<sup>1</sup> Johnson and Joyce, *THIS JOURNAL*, 38, 1385 (1916).

This salt was decomposed by treatment with an aqueous solution of alkali and the free pyrimidine extracted with ether. After removal of the ether the pyrimidine was converted into a double platinum chloride salt, which proved to be identical with the platinum salt of the base described in our previous paper.<sup>1</sup> It melted at 207–208° with decomposition.

**Behavior of 2-Methylmercapto-4,5-dibromodihydropyrimidine on Heating: The Formation of 2-Methylmercapto-5-bromopyrimidine (XXXI).**—Four grams of the 2-methylmercaptopyrimidine were dissolved in 20 cc. of carbon tetrachloride and the solution transferred to a pressure tube. Five grams of bromine, dissolved in 20 cc. of carbon tetrachloride, were then added and the tube sealed. The addition product separated almost at once in a crystalline condition. The tube was then heated at 100° for 10 hours. There was no pressure when it was opened, and underneath the colorless tetrachloride was a layer of a dark colored oil. The carbon tetrachloride was poured off and the solvent evaporated under diminished pressure, when we obtained a yellow liquid which solidified on cooling. This material weighed 1 g. This was triturated with ether, in which most of it dissolved, but leaving a small amount of solid material which was very soluble in water. The latter product was identified as the hydrobromic acid salt of 2-methylmercapto-5-bromopyrimidine. On evaporating the ether solution a crystalline substance was obtained which was easily purified by crystallization from dilute alcohol or a mixture of acetone and water and deposited in the form of transparent plates melting at 64–65°. It was identified as 2-methylmercapto-5-bromopyrimidine. This pyrimidine is insoluble in water, dilute alkali and dilute acids, but soluble in alcohol, ether and acetone.

Calc. for  $C_5H_5N_2SBr$ : N, 13.65%. Found: N, 13.49.

In another experiment the dibromo addition product was heated in a pressure tube at 125–135° for 4 hours. Under these conditions there was much more decomposition and a larger proportion of the hydrobromic acid salt of the bromopyrimidine was formed. In place of the dark-colored oil obtained in the previous case there was formed a black decomposition product which was not examined further. When the tube was opened there was some pressure due to the presence of hydrobromic acid and a crystalline substance was suspended in the carbon tetrachloride. This material was identified as the hydrobromide of 2-methylmercapto-5-bromopyrimidine and melted at 205–206°. It dissolved in water with dissociation into hydrobromic acid and the free 2-methylmercaptobromopyrimidine. The latter crystallized from dilute alcohol in the form of plates and melted at 65–6°.

<sup>1</sup> Johnson and Joyce, *Loc. cit.*

**Experimental Proof of the Structure of the Mercaptobromopyrimidine: 2-Methylmercapto-5-bromo-6-oxypyrimidine (XXVIII).**—This new pyrimidine was prepared in a similar manner as that employed by Wheeler and Johnson<sup>1</sup> for the preparation of the corresponding 2-ethylmercaptopyrimidine. Our procedure was as follows: Ten grams of 2-methylmercapto-6-oxypyrimidine were dissolved in 60 cc. of glacial acetic acid and 11.2 g. of bromine (in 20 cc. of glacial acetic acid) added slowly through a dropping funnel. The bromopyrimidine began to separate very quickly. After final addition of the bromine the mixture was allowed to stand for 2 hours and the bromopyrimidine then separated by filtration. It was purified by crystallization from alcohol and separated, on cooling, in the form of needles which melted at 239° with decomposition. The yield of purified pyrimidine was 10.6 g. or 70% of the theoretical.

Calc. for  $C_6H_5ON_2SBr$ : N, 12.67%. Found: N, 13.00.

**2-Methylmercapto-5-bromo-6-chloropyrimidine (XXX).**—This chloropyrimidine was obtained by the action of phosphorus oxychloride on the above mercaptopyrimidine. Nine grams of the mercaptopyrimidine were suspended in 25 cc. of the phosphorus halide and the mixture heated in an oil bath at 125° for 2 hours. Hydrochloric acid was evolved and the pyrimidine dissolved completely. The excess of phosphorus oxychloride was then removed by heating at 100° under diminished pressure, when we obtained the pyrimidine in the form of a thick oil. This was triturated with cold water to destroy any phosphorus halide present and the pyrimidine then extracted with ether and dried over anhydrous calcium chloride. After removing the ether, the bromochloropyrimidine was obtained as an oil which solidified on cooling. It crystallized from ether in the form of needles and melted at 44° to an oil.

Calc. for  $C_6H_4N_2SClBr$ : N, 11.69%. Found: N, 11.72.

**Reduction of 2-Methylmercapto-5-bromo-6-chloropyrimidine with Zinc Dust. The Formation of 2-Methylmercapto-5-bromopyrimidine.**—Three grams of the mercaptopyrimidine were dissolved in 25 cc. of alcohol (95 per cent.) and the solution diluted with 25 cc. of water. To the slightly turbid solution 5 g. of zinc dust were added. There was an indication immediately that there was partial reduction, because the zinc dust assumed a granular or flaky condition. The mixture was digested under reflux condenser for 15 minutes, cooled and finally filtered to remove the excess of zinc. The alcohol and water were then removed by evaporation under diminished pressure, when we obtained an oil which was insoluble in water. This was dissolved in ether and dried over anhydrous calcium chloride. When the ether was evaporated an oil was obtained which did not solidify after standing for several days in a vacuum over sulfuric

<sup>1</sup> *Am. Chem. J.*, 31, 603 (1904).

acid. In order to isolate the 5-bromopyrimidine this oil was treated with concentrated hydrobromic acid, when the hydrobromide of the pyrimidine separated at once in a crystalline condition. On dissolving this in alcohol it underwent dissociation, and after cooling the solution the 2-methylmercapto-5-bromopyrimidine separated in the form of needles. They melted at  $65^{\circ}$  to an oil. The yield of this pyrimidine was 1 g.

Calc. for  $C_6H_6N_2SBr$ : N, 13.65%. Found: N, 13.60.

**The Addition of Bromine to 2-Ethylmercaptopyrimidine.**—Bromine combines with this pyrimidine in carbon tetrachloride solution at ordinary temperature. Two and three-tenths grams of bromine dissolved in 20 cc. of the tetrachloride were added to a cold solution of 2 g. of the pyrimidine in 20 cc. of carbon tetrachloride. The resulting mixture was then cooled to  $0^{\circ}$  with ice-water and allowed to stand for several hours at this temperature. The addition product did not separate in a crystalline condition as in the case of the 2-methylmercaptopyrimidine but deposited as a dark colored oil which showed no sign of crystallizing on standing. The carbon tetrachloride was removed by evaporation under diminished pressure and the oil again allowed to stand for several days in a desiccator, but it still showed no evidence of solidifying and was used for the following experiments:

**Action of Acetone and the Crude Addition Product. The Formation of 2-Ethylmercaptopyrimidine (XXV).**—This addition product interacts immediately with acetone at ordinary temperature, giving monobromoacetone and the hydrobromic acid salt of this pyrimidine. On mixing the two reagents and allowing to stand this hydrobromide deposits in the form of prisms. It was purified by crystallization from alcohol and melted at  $140-141^{\circ}$ . A mixture of this salt with that originally prepared by Johnson and Joyce<sup>1</sup> melted at the same temperature.

Calc. for  $C_6H_6N_2S.HBr$ : N, 12.67. Found: N, 12.35, 12.40.

**Conversion of the Addition Product into 2-Ethylmercapto-5-bromopyrimidine (XXIX).**—This new pyrimidine is formed by heating 2-ethylmercaptopyrimidine (2 g.) with the required amount of bromine in carbon tetrachloride solution for 10 hours at  $125-130^{\circ}$ . When the bomb tube was opened there was pressure due to the presence of hydrobromic acid and a dark tarry product adhered to the sides of the tube. Suspended in the tetrachloride was a considerable amount of material crystallized in the form of needles, which melted at  $180^{\circ}$  with decomposition. This was the hydrobromic acid salt of 2-ethylmercapto-5-bromopyrimidine. It was very soluble in water and on warming the solution immediately underwent dissociation. When the salt was dissolved in hot, dilute alcohol and the solution cooled the free base separated in the form of

<sup>1</sup> *Loc. cit.*

needles melting at  $43-5^{\circ}$  to an oil. The substance contained sulfur and bromine and a nitrogen determination agreed with the calculated value for 2-ethylmercapto-5-bromopyrimidine.

Calc. for  $C_6H_7N_2SBr$ : N, 12.78. Found: N, 12.90.

When the carbon tetrachloride was evaporated more of this same base was obtained and melted at  $43-45^{\circ}$ .

UNITED STATES DEPARTMENT OF AGRICULTURE.]

## SOME NUMERICAL RELATIONS AMONG THE ROTATORY POWERS OF THE COMPOUND SUGARS.

By C. S. HUDSON.

Received June 8, 1916.

The general group of polysaccharides includes many pure crystalline substances of definite chemical individuality, such as the di-, tri-, and tetrasaccharides, together with a series of amorphous products, such as starch, glycogen, inulin, cellulose, pentosans, mannans, galactans, etc. To distinguish the pure crystalline polysaccharides from their less definitely characterized relatives, it is suggested that they be classed under the group name of *compound sugars*, a designation which separates them very well also from the simple sugars, or monosaccharides, into which they may be decomposed by hydrolysis. In the present article, it is sought to extend to several of the compound sugars the numerical relationships that have been found to hold among the rotatory powers of the alpha and beta forms of the monosaccharides and their glucosidic derivatives.<sup>1</sup>

### Sugars of the Sucrose Group.

**Known Members of the Group.**—The trisaccharide raffinose may be split by complete hydrolysis into its three component simple sugars, galactose, glucose and fructose; by partial hydrolysis, best through the agency of enzyme action, it may be split either into fructose and melibiose (= galactose < glucose <<sup>2</sup>) by the use of invertase or weak acids, or into galactose and sucrose (= glucose < > fructose) by the aid of emulsin. Raffinose may accordingly be regarded as galactose < glucose < > fructose, a derivative of sucrose, a combination between that sugar and galactose. Other sugars which are now regarded as derivatives of sucrose are<sup>3</sup> gentianose (= glucose < glucose < > fructose) and stachyose (= galactose <

<sup>1</sup> THIS JOURNAL, 31, 66 (1909).

<sup>2</sup> The symbol < denotes the carbonyl or lactonyl group. See THIS JOURNAL, 31, 661 (1909). The term lactonyl, which has been suggested by S. F. Acree (*Science*, 42, 101 (1915)) to indicate an aldehyde or ketone group that has formed a lactone-like ring, as in the sugars, seems very appropriate.

<sup>3</sup> Bourquelot and Bridel, *Compt. rend.*, 152, 1060 (1911).

*galactose* < *glucose* > *fructose*). It will be convenient to designate sucrose and its three derived compound sugars as members of the sucrose group. The evidence that gentianose and stachyose belong in the group is not direct and conclusive as in the case of raffinose, though it appears convincing, as will be seen. The action of invertase upon either sucrose or raffinose causes specific hydrolysis of the union between glucose and fructose, which may be designated the *sucrose union*. Invertase may be regarded therefore, as a specific hydrolyst of the "sucrose union," and the action of this enzyme upon a compound sugar may be taken as evidence that the sugar contains the "sucrose union" and is a derivative of sucrose. Bourquelot and Hérissé<sup>1</sup> have shown that invertase splits gentianose into fructose and gentiobiose (= *glucose* < *glucose* <) and C. Tanret<sup>2</sup> has shown that it splits stachyose into fructose and manninotriose (= *galactose* < *galactose* < *glucose* <), hence these sugars are considered to be derivatives of sucrose. Recently Bourquelot and Bridel<sup>3</sup> have isolated a new crystalline compound sugar, verbascose, which is hydrolyzed by invertase to fructose and another sugar, not yet isolated; probably verbascose belongs in the sucrose group.

**Rotatory Relationships in the Sucrose Group.**—The fact that sucrose is not a reducing sugar indicates that the lactonyl hydroxyl groups of its two constituents are bound in glucosidic union, and the further fact that only one molecule of water per molecule of sucrose becomes combined during hydrolysis shows that the groups in question are joined with each other, because if the union were otherwise, two molecules of water per molecule of sugar would be used up. The same conclusion may be drawn from the fact that sucrose yields an octacetate and contains, therefore, eight hydroxyl groups per molecule. The structure of sucrose is accordingly generally considered to be

In this formula it is assumed that the lactonyl ring is upon the gamma carbon in both hexoses, which appears likely, but the following argument would not be affected if these rings should prove to be in other positions:<sup>4</sup> Let G represent the rotation due to the glucose chain, not including,

<sup>1</sup> *J. pharm. chim.*, [6] 13, 305 (1901).

<sup>2</sup> *Bull. soc. chim.*, 27, 955 (1902). See also Vintilesco, *J. pharm. chim.*, 30, 167 (1909).

<sup>3</sup> *Compt. rend.*, 151, 760 (1910).

<sup>4</sup> What really is assumed, as will be understood from the continuation, is that the glucose lactonyl ring in sucrose is upon the same carbon atom as in the case of the alpha and beta forms of glucose.

however, the asymmetric lactonyl carbon of rotation  $B'$ , and let  $F$  be the rotation of the fructose residue. Summing these values the molecular rotation of sucrose may be written  $[M]_S = G + B' + F$ . According to this plan the molecular rotations of the members of the sucrose group may be formulated as follows, when (Mb), (Gb) and (Mn) indicate the rotations of the melibiose, gentiobiose and manninotriose chains, respectively:

Parent sugar.	Hydrolytic products with invertase.	Molecular rotation of the parent sugar.
Sucrose (M.W. 342)	Glucose (180) + Fructose (180)	$G + B' + F$ (1)
Raffinose (504)	Melibiose (342) + Fructose	$(Mb) + B' + F$ (2)
Gentianose (504)	Gentiobiose (342) + Fructose	$(Gb) + B' + F$ (3)
Stachyose (666)	Manninotriose (504) + Fructose	$(Mn) + B' + F$ (4)

Subtracting the molecular rotation of sucrose from that of raffinose,  $[M]_R$ , gives

$$[M]_R - [M]_S = (Mb) - G. \quad (5)$$

The specific rotation of sucrose is  $+66.5$ , and its molecular rotation  $(66.5)(342) = +22700 = [M]_S$ . In the article first cited it was shown that  $G$  may be obtained as half the *sum* of the molecular rotations of the alpha and beta forms of glucose, which gives the value  $+11900$  if the specific rotations of the two forms of glucose are taken as  $113^1$  and  $19.^2$  Introducing these values in Equation 5 and transposing gives

$$(Mb) = [M]_R - 10800. \quad (6)$$

To pass now from (Mb) to the rotation of either the alpha or beta form of melibiose it is necessary to add the rotation of the end asymmetric lactonyl carbon atom of melibiose. It has been shown in the former article that the rotation of this carbon is equal to half the *difference* of the molecular rotations of the alpha and beta forms of glucose, or  $8460$ , hence the molecular rotations of the forms of melibiose are written:

$$\text{Molecular rotation of } \alpha\text{-melibiose} = (Mb) + 8460 = [M]_R - 2340$$

$$\text{Molecular rotation of } \beta\text{-melibiose} = (Mb) - 8460 = [M]_R - 19300$$

Similar equations with the same numerical terms express the same relation between the molecular rotations of gentiobiose and gentianose, and of manninotriose and stachyose. *For the sugars of the sucrose group that are hydrolyzed by invertase to yield fructose and an aldose, the molecular rotation of the aldose is less than that of its parent sugar by 2340 for its alpha form and 19300 for its beta modification.* The rotatory powers of melibiose, gentiobiose, and manninotriose may be calculated by this relation.

**The Rotation of Melibiose.**—Since the specific rotation of raffinose is  $+123$ , its molecular rotation is  $+62000$ , and the molecular rotations of the alpha and beta forms of melibiose are calculated from the foregoing relation to have the values  $+59700$  and  $+42700$ , respectively, and from

<sup>1</sup> Hudson and Yanovsky, forthcoming publication.

<sup>2</sup> Hudson and Dale, forthcoming publication.

these the specific rotations are found to be  $+175^{\circ}$  and  $+125^{\circ}$ . The latter value agrees almost exactly with Loiseau's<sup>1</sup> measurement of the initial specific rotation of  $\beta$ -melibiose (124), and recently E. Yanovsky and the writer,<sup>2</sup> in repeating the measurement, have obtained the same value as Loiseau. The alpha form of melibiose has never been prepared in a pure state and the only experimental value known for its specific rotation is that which Yanovsky and the author have found indirectly through a measurement of the increase in solubility of  $\beta$ -melibiose during its mutarotation. Our value is  $+179^{\circ}$ .<sup>2</sup> The agreement is very good in view of the indirectness of the experimental measurement.

**The Rotation of Gentiobiose.**—The specific rotation of gentianose is  $+31$ ,<sup>3</sup> hence its molecular rotation is  $+15600$  and the specific rotations of the alpha and beta forms of gentiobiose may be calculated by the method which has just been followed to be  $+39$  and  $-11$ , respectively. Bourquelot and Hérissé<sup>4</sup> record  $+9.8$  as the final specific rotation of gentiobiose, a value which refers to the equilibrium in solution between the alpha and beta forms of the sugar. By crystallizing gentiobiose from methyl alcohol they obtained a crystalline derivative of it containing two molecules of methyl alcohol of crystallization. This substance had an initial specific rotation in water of about  $+18$ , decreasing to  $+9.8$  (both numbers are referred to the solvent-free sugar, m. w. 342) on standing. By crystallizing gentiobiose from ethyl alcohol solution they prepared the crystalline sugar itself, which had a specific rotation of  $-6$  six minutes after dissolving, changing likewise to  $+9.8$  on standing. If one extrapolates as well as possible the value  $-6$  back through the first six minutes according to the rate of mutarotation that Bourquelot and Hérissé observed a value near the calculated  $-11$  is obtained. It would seem that the alpha form of melibiose which they evidently had in hand in the form of a compound with methyl alcohol of crystallization contained some of the beta modification.

**The Rotation of Manninotriose.**—The specific rotation of stachyose being  $+148$ ,<sup>5</sup> its molecular rotation is  $+98600$ , and hence the specific rotations of the alpha and beta forms of manninotriose are calculated to be  $+191$ , and  $+157$ , respectively. These rotations do not appear to have ever been measured but C. Tanret<sup>6</sup> records  $+167$  as the final specific rotation of manninotriose. This value lies between the calculated numbers, as should be the case, and is also at approximately the same position between them as in the case of glucose, melibiose and gentiobiose. The

<sup>1</sup> *Z. Ver. Zuckerind.*, **52**, 1050-9 (1903).

<sup>2</sup> Forthcoming publication.

<sup>4</sup> *J. pharm. chim.*, [6] **16**, 418 (1902).

<sup>5</sup> Schulze and Planta, *Ber.*, **24**, 2705 (1890).

<sup>6</sup> *Bull. soc. chim.*, [3] **29**, 891 (1903).

ratio of the concentrations of the beta and alpha forms which are present at equilibrium is for glucose  $(113 - 52^3)/(52 - 19) = 1.8$ , for melibiose  $(175 - 143^3)/(143 - 124) = 1.6$ , for gentiobiose  $(39 - 10^3)/(10 + 11) = 1.3$ , and for manninotriose  $(191 - 167^1)/(167 - 157) = 2.4$ . If the final rotation of manninotriose were 169 rather than 167 the ratio would be the same as for glucose, and if it were 172 the ratio would be the same as for gentiobiose.

**Other Possible Members of the Sucrose Group.**—Since lactose, cellose, and maltose have structures in which the free lactonyl hydroxyl is a part of the glucose group, it is conceivable that these disaccharides might be united with fructose through a sucrose union to yield derivatives of sucrose. The expected specific rotations of these compounds can be calculated according to the preceding considerations. For example, since the specific rotation of  $\beta$ -lactose (m. w. 342) is  $+35$ , its molecular rotation is  $+12000$ , and the specific rotation of the hypothetical  $\alpha$ -lactose  $< > \alpha$ -fructose (m. w. 504) is calculated to be  $(12000 + 19300)/504 = +62$ .

**The Acetylated Sugars of the Sucrose Group.**—Referring back to the structural formula for sucrose, consider the rotation of sucrose octacetate. Its molecular rotation is the sum of a new quantity  $G'$ , which is the rotation of an acetylated glucose chain, plus  $B''$ , which may possibly be different in value from  $B'$ , plus  $F'$ , the rotation of an acetylated fructose residue. In the same way that  $G$  was obtained from the specific rotations of the alpha and beta forms of glucose  $G'$  may be found from those of the corresponding glucose pentacetates (m. w. 390), which have the values  $+102$  and  $+4$ , respectively, in chloroform solution.<sup>3</sup> Half of the sum of their molecular rotations is  $+20700 = G'$ , and half the difference is  $+19100$ , the latter being the rotation of the end asymmetric carbon in glucose pentacetate. The specific rotation of sucrose octacetate (m. w. 678) in chloroform is  $+59.6$ ,<sup>3</sup> and hence its molecular rotation is  $+40400$ . The molecular rotation of the glucose pentacetate chain is therefore 19700 less than that of sucrose octacetate or the molecular rotation of  $\alpha$ -glucose pentacetate is  $(19700 - 19100) = 600$  less than that of sucrose octacetate, while that of the  $\beta$ -pentacetate is  $(19700 + 19100) = 38800$  less. These numerical differences apply also to the molecular rotations of the corresponding acetylated derivatives of the pairs raffinose and melibiose, gentianose and gentiobiose, stachyose and manninotriose. The beta octacetates (m. w. 678) of melibiose and gentiobiose have the specific rotations  $+102^4$  and  $-5$ ,<sup>5</sup> respectively, in chloroform solution. From

<sup>1</sup> Final specific rotations of the sugars.

<sup>2</sup> Hudson and Dale, *THIS JOURNAL*, **37**, 1265 (1915).

<sup>3</sup> Hudson and Johnson, *Ibid.*, **37**, 2753 (1915).

<sup>4</sup> Hudson and Johnson, *Ibid.*, **37**, 2752 (1915).

these data the specific rotations of the hendecacetates (m. w. 966 and formula  $C_{28}H_{21}(C_2H_3O)_{11}O_{16}$ ) of raffinose and gentianose in chloroform are calculated to be +112 and +43, respectively. Scheibler and Mittelmeier<sup>1</sup> have found +92 for crystalline raffinose hendecacetate in alcohol, but the value in chloroform is not known. It is probably higher than +92, because the specific rotation of sucrose octacetate in chloroform is +60 (see preceding) and in alcohol, +38.<sup>2</sup> Gentianose hendecacetate does not appear to have ever been prepared.

### Sugars of the Trehalose Group.

**Trehalose and Isotrehalose.**—Since trehalose is not a reducing sugar, combines with only one molecule of water per molecule of sugar during hydrolysis, and also forms an octacetate, its structure may be considered to be *glucose* < > *glucose*, the lactonyl hydroxyls being united with the elimination of water. The three possible combinations which fit this structure, assuming gamma-lactonyl rings, are  $\alpha$ -*glucose* < >  $\alpha$ -*glucose*, the  $\alpha,\beta$  form, or the  $\beta,\beta$  form. If G represents the rotation of the glucose chain, as before, and A' that of the asymmetric lactonyl carbon (+A' for the  $\alpha$ -glucoside form and -A' for the  $\beta$ ) the molecular rotations of the three combinations may be formulated:

$$\alpha,\alpha\text{-Trehalose} \dots\dots\dots G + A' + A' + G = 2G + 2A'$$

$$\alpha,\beta\text{-Trehalose} \dots\dots\dots G + A' - A' + G = 2G$$

$$\beta,\beta\text{-Trehalose} \dots\dots\dots G - A' - A' + G = 2G - 2A'$$

The value of 2G has already been found from the sum of the molecular rotations of the alpha and beta forms of glucose to be +23800, and hence the specific rotation of  $\alpha,\beta$ -trehalose (m. w. 342) is calculated to be +70. This value is entirely different from the observed specific rotation of trehalose, +197, hence the natural sugar is not the  $\alpha,\beta$  combination. Neither can it be the  $\beta,\beta$  form because it should then be less dextrorotatory than +70 since the value of -A' for the known  $\beta$ -glucosides is a quantity of considerable magnitude. On the other hand, the high dextrorotation of trehalose agrees well with what would be expected for  $\alpha$ -*glucose* < >  $\alpha$ -*glucose*. Assuming this to be the structure of the natural sugar, its molecular rotation ( $197 \times 342 = +67400$ ) is  $2G + 2A'$ , and since 2G is +23800, 2A' is +43600, and the molecular rotation of  $\beta,\beta$ -trehalose ( $2G - 2A'$ ) may be calculated to be -19800, and the specific rotation -58. Under the name *isotrehalose*, Fischer and Delbrück<sup>3</sup> have recently described a sugar of the trehalose type which they prepared by the saponification of crystalline *isotrehalose octacetate*, a substance which in its turn was made by the condensation of bromo-acetyl glucose. Isotrehalose was not obtained in a crystalline state and the amorphous sub-

<sup>1</sup> Ber., 23, 1443 (1890).

<sup>2</sup> Herzfeld, *Ibid.*, 13, 267 (1880).

<sup>3</sup> Ber., 42, 2776 (1909).

stance was not free from ash. Under such conditions the specific rotation of the impure material can only be considered as an approximate value of the rotation of the pure sugar. Fischer and Delbrück found  $-39$ , a value which strongly suggests that isotrehalose is  $\beta,\beta$ -trehalose. This view is supported by the fact that all other derivatives that have been prepared from bromo-acetyl glucose belong to the  $\beta$  series. It is also supported by the result of the following considerations, which indicate that the parent substance, *isotrehalose octacetate*, is a  $\beta,\beta$  form.

**Octacetates of the Trehalose Sugars.**—The relations which have just been derived among the rotations of the three trehaloses and the alpha and beta forms of glucose apply likewise to the fully acetylated derivatives of these five substances. Thus the molecular rotation of  $\alpha,\beta$ -trehalose octacetate may be regarded equal to the sum of the molecular rotations of the alpha and beta glucose pentacetates, which is known to be  $+41400$ , and its specific rotation (m. w. 678) in chloroform is calculated to be  $+61$ . The observed specific rotation of pure trehalose octacetate in chloroform is  $+162$ ,<sup>1</sup> which indicates again that trehalose is the  $\alpha,\alpha$  form. The specific rotation of the  $\beta,\beta$  form, or isotrehalose octacetate, is calculated from these two rotations, by the same method that was used with the sugars, to be  $-40$  in chloroform. Fischer and Delbrück found  $-17$  in benzene, a difference which may be due to the change of solvent, because trehalose octacetate rotates  $-162$  in chloroform and  $+171$  in benzene.<sup>2</sup>

**Other Compound Sugars of the Trehalose Type.**—It may be useful to indicate that the rotation of nearly all the possible sugars of this type may be calculated from existing data. As an illustration consider the tetrasaccharide *lactose*  $\langle \rangle$  *lactose*, a combination which E. Fischer and H. Fischer<sup>3</sup> have sought to prepare through the condensation of bromo-acetyl lactose. Since the alpha and beta forms of lactose (m. w. 342) rotate  $+86$  and  $+35$ , respectively, twice the molecular rotation of the lactose chain is  $+41400$ . Since the molecular weight of the tetrasaccharide is 666, the specific rotation of its  $\alpha,\beta$  form is calculated to be  $41400/666 = +62$ . Assuming that the asymmetric lactonyl carbons uniting the glucose residues have the same rotations that were found for them in trehalose,  $2A' = +44000$ , and hence the specific rotation of the  $\alpha,\alpha$  form of the tetrasaccharide is calculated to be  $(41400 + 44000)/666 = +128$ , and that of the  $\beta,\beta$  form  $(41400 - 44000)/666 = -4$ .

From the specific rotations of the alpha and beta lactose octacetates (m. w. 678),  $+54$  and  $-4$  in chloroform,<sup>4</sup> and the value  $+68500$  for the

<sup>1</sup> Hudson and Johnson, *THIS JOURNAL*, 37, 2752 (1915).

<sup>2</sup> Measured recently in this laboratory by Dr. J. M. Johnson.

<sup>3</sup> *Ber.*, 43, 2532 (1910).

<sup>4</sup> Hudson and Johnson, *THIS JOURNAL*, 37, 1273 (1915).

two lactonyl carbons (calculated as in the case of the trehalose octacetates), the specific rotation of the fully acetylated derivatives (m. w. 1255) of *lactose* < *lactose* may be calculated to be, for the  $\alpha, \beta$  form  $+33900/1255 = +27$ , for the  $\alpha, \alpha$  form  $(33900 + 68500)/1255 = +82$ , for the  $\beta, \beta$  form  $-28$ . The similar derivatives of maltose and cellose can be treated in the same way. The calculations are here indicated because the work of E. Fischer with H. Fischer, and Zemplén<sup>2</sup> appear to open a way for synthesizing these compounds of lactose, maltose and cellose, respectively, when sufficient material is available.

Lastly, the expected specific rotation of  $\beta, l\text{-arabinose}$  <  $\beta, l\text{-arabinose}$  (m. w. 282) may be calculated from the specific rotations of the alpha and beta forms of the sugar,  $+76$  and  $+184$ , respectively, to be  $((76 + 184) 150 + 44000^3)/282 = +294^\circ$ . This rotation is of interest because it appears to be the largest specific rotation that can be expected among the sugars from present data.

### The Related Rotations of Lactose and Cellose.

There are three disaccharides which have the general structure *glucose* < *glucose* <, namely, maltose, cellose and gentiobiose, and two of the composition *galactose* < *glucose* <, namely, melibiose and lactose. In these structures the place of attachment of the left hand glucose or galactose molecule is evidently its lactonyl carbon, but several points of union for the right hand glucose molecule are possible. Without more knowledge of this point of attachment for each of the compound sugars, it does not seem possible in general to obtain relations among their rotatory powers. However, there is one special case which can be adequately treated at present and it leads to an interesting relation between the rotations of lactose and cellose. The structures shown above indicate that for each point of attachment in the right hand glucoside residue, there can be four related sugars according as the left hand member is  $\alpha$ - or  $\beta$ -glucose, or  $\alpha$ - or  $\beta$ -galactose. To formulate the rotations of these forms let  $G$  and  $G_a$ , respectively, be the rotations of the left hand glucose and galactose chains,  $L$  that of their bound lactonyl carbons, and  $R$  that of the common right hand glucose residue. Since the free lactonyl group of this residue permits  $\alpha$  and  $\beta$  forms, let  $R$  refer throughout to the same one of these. The molecular rotations of the four structures are thus:

$$\begin{array}{ll}
 \alpha\text{-galactose} < \text{glucose} < = G_a + L + R & \beta\text{-galactose} < \text{glucose} < = G_a - L + R \\
 \alpha\text{-glucose} < \text{glucose} < = G + L + R & \beta\text{-glucose} < \text{glucose} < = G - L + R
 \end{array}$$

---

$$\begin{array}{ll}
 \text{Difference } G_a - G & G_a - G
 \end{array}$$

<sup>1</sup> *Loc. cit.*

<sup>2</sup> *Ber.*, 43, 2536 (1910).

<sup>3</sup> The assigning of a positive rather than negative sign to 44,000 (= 2A), although the compound is a  $\beta$ -derivative, is made because the arabinose is the *levo* form. See *THIS JOURNAL*, 31, 72 (1909).

The differences are equal to each other, and as will be seen readily are also equal to the difference of the molecular rotations of the corresponding  $\alpha$  and  $\beta$  forms of galactose and glucose, or of methyl galactoside and methyl glucoside. We reach the conclusion, therefore, that if either of the *galactose* < *glucose* < sugars (melibiose or lactose) has a structure in which the right hand glucose residue is identical with the similar component of one of the *glucose* < *glucose* < sugars (maltose, cellose or gentiobiose) the pair of sugars, in case both are  $\alpha$ -glucosidic compounds or both beta, should differ in molecular rotation by the difference between the molecular rotations of the galactose and glucose chains. The difference in specific rotation of  $\beta$ -methyl galactoside ( $0^\circ$ ) and  $\beta$ -methyl glucoside ( $-32^\circ$ ) (of m. w. 194) is  $+32^\circ$ , which amounts to  $(32)(194)/342 = +18^\circ$  in the specific rotation of the disaccharides (m. w. 342). If  $+18$  be added to the specific rotation of the beta forms of maltose ( $+118$ )<sup>1</sup> and of gentiobiose ( $-11$ ) the sums,  $+136$  and  $+7$  do not agree with the rotations of either  $\beta$ -melibiose ( $+124$ ) or  $\beta$ -lactose ( $+35$ ). On the other hand, the rotation of  $\beta$ -cellose ( $+16$ )<sup>1</sup> plus  $18$  is equal to that of  $\beta$ -lactose ( $35$ ) almost exactly.

**The Rotations of the Octacetates of These Sugars.**—It is highly desirable to test in independent ways this conclusion, that lactose and cellose have the same structure for their common glucose residue, and that the galactose residue of one belongs to the same series (probably the  $\beta$ , judging from the low rotation of lactose) as the glucosidic glucose residue of the other. If the similarity does exist, it would be expected to extend to many derivatives of these sugars, and it should be possible to decide from a comparison of the rotations of each pair of derivatives whether the agreement that has been found to hold for the parent sugars is a general one and really has for its basis the assigned reason, or is an accidental agreement in the one case tested. The rotations in chloroform solution of the pure octacetates of the disaccharides in question are known, and a comparison of them appears to be of special value because in them the rotations of the individual asymmetric carbon atoms in the glucose residue are doubtless quite different from the values for the sugars themselves. The difference between the specific rotations of tetra-acetyl  $\beta$ -methyl galactoside ( $-13$ )<sup>1</sup> of m. w. 362, and the corresponding acetylated  $\beta$ -methyl glucoside ( $-18$ )<sup>2</sup> is  $+5$ , which corresponds to  $(5)(362)/678 = 3^\circ$  for the disaccharide octacetates. The addition of this value to the specific rotation of  $\beta$ -maltose octacetate ( $+63$ ) gives a sum entirely different from the rotation of the  $\beta$ -octacetate of either melibiose ( $+102$ ) or lactose ( $-4$ ). On the other hand, the rotations of the  $\beta$ -octacetates of both cellose ( $-15$ ) and gentiobiose ( $-5$ ) yields sums ( $-12$  and  $-2$ ).

<sup>1</sup> Hudson and Yanovsky, forthcoming publication.

<sup>2</sup> Hudson and Dale, *THIS JOURNAL*, 37, 1265 (1915).

which are near the rotation of  $\beta$ -lactose octacetate ( $-4$ ). The combination of this result with that obtained from the rotations of the sugars themselves, in which gentiobiose was clearly ruled out, gives strong evidence that the common glucose residues of lactose and cellose have identical structure.

## THE ISOMERIC ALPHA AND BETA HEXACETATES OF $\alpha$ -GLUCOHEPTOSE.

By C. S. HUDSON AND E. YANOVSKY.<sup>1</sup>

Received June 19, 1916.

E. Fischer<sup>2</sup> has shown that two isomeric fully acetylated derivatives of  $\alpha$ -glucoheptose could be prepared by the action of acetic anhydride on the sugar. When sodium acetate was used to catalyze the reaction, the crystalline product was a hexacetate which melted at  $132^\circ$ , but the use of zinc chloride gave an isomeric hexacetate of m. p.  $156^\circ$ . Fischer has mentioned that these isomeric hexacetates of  $\alpha$ -glucoheptose are produced by the same reactions which yield the alpha and beta pentacetates of glucose. Since the isomerism of the glucose pentacetates can be explained, according to Fischer,<sup>3</sup> as due to the existence of the structures that are now generally named the alpha and beta forms, it appears probable that the similarly produced hexacetates of  $\alpha$ -glucoheptose have the corresponding structures:

in which the asymmetry of the right-hand terminal carbon atom permits the two configurations. If this view is correct, the molecular rotatory power of the alpha form may be written  $+A + B'$ , and that of the beta form  $-A + B'$ , where  $A$  is the rotation of the terminal asymmetric carbon and  $B'$  is that due to the remainder of the structure.<sup>4</sup> It follows then that the difference of the molecular rotations of the two forms is  $2A$ , which is the same as the difference in the molecular rotations of the alpha and beta pentacetates of glucose, of rotations  $+A + B$  and  $-A + B$ , respectively. The rotations of the  $\alpha$ -glucoheptose hexacetates are not recorded in Fischer's article, and we have consequently prepared the sub-

<sup>1</sup> Contribution from the Carbohydrate Laboratory, Bureau of Chemistry, United States Department of Agriculture.

<sup>2</sup> *Ann.*, 270, 64 (1892); *Ber.*, 26, 2400 (1893).

<sup>3</sup> *Ber.*, loc. cit.

<sup>4</sup> Hudson, *THIS JOURNAL*, 31, 66 (1909).

stances in pure condition and have found the following rotatory powers in chloroform:<sup>1</sup>

$$\begin{array}{l} \alpha\text{-Hexacetyl } \alpha\text{-glucoheptose, } [\alpha]_D^{20} = +87.0, [M]_D^{20} = +40,200^2 = +A + B' \\ \beta\text{-Hexacetyl } \alpha\text{-glucoheptose, } [\alpha]_D^{20} = +4.8, [M]_D^{20} = +2,200 = -A + B' \end{array}$$

---

$$\text{Difference} = 38,000 = 2A$$

The corresponding values for the glucose pentacetates in the same solvent have been found<sup>3</sup> to be

$$\begin{array}{l} \alpha\text{-Pentacetyl glucose, } [\alpha]_D^{20} = +101.6, [M]_D^{20} = +39,600^2 = +A + B \\ \beta\text{-Pentacetyl glucose, } [\alpha]_D^{20} = +3.8, [M]_D^{20} = +1,500 = -A + B \end{array}$$

$$\text{Difference} = 38,100 = 2A$$

The agreement of the values for 2A is a close one, the discrepancy of 100 amounting to only about 0.25° in specific rotation, which is well within the limits of experimental error. There is thus good evidence that the two hexacetates constitute an alpha and beta pair, and this is supported by the fact, which is described later on, that the lower rotating one may be readily transformed into the other by warming it in acetic anhydride solution with a little zinc chloride, a method which has been found in general to change beta acetates to the corresponding alpha isomers. Since  $\alpha$ -glucoheptose is a derivative of *d*-glucose, its more dextro-rotatory hexacetate ( $[\alpha]_D^{20} = +87^\circ$ ) is to be named<sup>4</sup> the alpha form, and the other ( $[\alpha]_D^{20} = +5$ ) the beta modification.

### Experimental.

**Preparation of the Beta Hexacetate of  $\alpha$ -Glucoheptose.**—A mixture of one part anhydrous sodium acetate, four parts  $\alpha$ -glucoheptose, and 16 parts acetic anhydride was heated until the sugar dissolved, and then poured into an excess of cold water. An insoluble sirup precipitated and soon crystallized, crystals also separating from the solution. On recrystallizing the product from hot water a yield equal to 75% of the weight of sugar taken was obtained. Recrystallization from 50% alcohol is a more effective way to obtain the beta hexacetate entirely free from the alpha isomer. After two recrystallizations from this solvent, the material showed the specific rotation of  $[\alpha]_D^{20} = +4.8$  in chloroform, a value which did not change with further recrystallization. The substance melted at 135°, uncorrected. Its elementary composition has been established by Fischer. For the acetyl determination, samples of 0.3092 and 0.2680 g. were boiled with 50 cc. 0.25 *N* H<sub>2</sub>SO<sub>4</sub> three hours in a quartz flask with

<sup>1</sup> *Chloroformum purificatum*, U. S. P., was used in all the measurements of the rotations.

<sup>2</sup> The molecular weight of the hexacetate is taken as 462, that of glucose pentacetate 390.

<sup>3</sup> Hudson and Dale, *THIS JOURNAL*, 37, 1264 (1915).

<sup>4</sup> See *THIS JOURNAL*, 31, 72 (1909).

a quartz reflux condenser, yielding 55.6 and 56.0% acetyl ( $\text{CH}_3\text{CO}$ ) in comparison with 55.8, the calculated value for a heptose hexacetate.

**Preparation of the Alpha Hexacetate of  $\alpha$ -Glucoheptose.**—Since it has already been shown by Fischer that this isomer is produced through the acetylation of the sugar with hot acetic anhydride and zinc chloride, we sought to obtain it by a method which has frequently been used in this laboratory to prepare alpha acetates, namely, by heating the acetic anhydride solution of the beta acetate with a little zinc chloride. Ten grams of the beta hexacetate were dissolved in 100 cc. acetic anhydride containing 2 g.  $\text{ZnCl}_2$ . The specific rotation of this solution was  $-10^\circ$  to begin with, but after heating it three hours on the steam bath its rotation became constant at  $+25$ , indicating that the equilibrium in this solvent between the alpha and beta forms of the hexacetate had been established. On pouring the mixture into cold water an insoluble sirup precipitated and soon crystallized. The aqueous solution was extracted with chloroform, the extract washed with sodium bicarbonate solution and with water, and the crystals which formed when the chloroform was evaporated were united with those from the insoluble mass. One recrystallization from hot water of this product yielded crystals which had a specific rotation of  $+32$ , but on recrystallizing then five times from ether, a constant specific dextrorotation of  $+87.0^\circ$  in chloroform was found. The pure substance melted at  $164^\circ$ , uncorrected, which is higher than the value found by Fischer,  $156^\circ$ , but our material was probably more nearly free from the beta isomer. Two acetyl estimations gave 55.6 and 55.5%  $\text{CH}_3\text{CO}$  in comparison with the calculated value 55.8.

## TRIPHENYLMETHYL. XXVI. TAUTOMERISM OF TRIARYL-CARBINOLS.

BY M. GOMBERG AND N. E. VAN STONE.

Received June 12, 1916.

### I. Introduction.

**Historical.**—The historical development of the application of the tautomeric hypothesis to the triphenylmethane derivatives may be said to fall mainly within the following periods:

(1) The complex dyes were considered as possessing of necessity a radically different constitution from that of the corresponding triaryl-carbinols, for the very reason of the striking difference in properties. The dyes were *assumed* to possess a quinonoid constitution (I) in contradistinction from the benzenoid constitution of the carbinols (III). The possible existence of compounds isomeric with the carbinols but themselves colored and quinonoid, or the existence of salts isomeric with the

dyes but colorless and benzenoid, was neither looked for nor suspected. The hypothesis of tautomerism had no consideration in the discussion of the constitution of the dyes.

(2) With the advent of the tautomeric hypothesis the constitution of the dyes became a subject of new interest. Hantzsch and his coworkers<sup>1</sup> have shown that crystal violet and other similar dyes, in solution, produce on addition of alkali, a colored, water-soluble base, which, like the original ammonium salt, is still dissociated to an appreciable extent and which only eventually changes over to the colorless, insoluble, non-dissociated carbinol. Hantzsch drew the conclusion that the water-soluble transitory compound possessing a marked electrical conductivity must be the true ammonium base. It, therefore, represents the labile desmotropic form (II), while the carbinol subsequently precipitating from the solution is the stable tautomer (III). In Hantzsch's nomenclature this evanescent ammonium hydroxide compound is the true base, while the stable carbinol is the *pseudo-base*. Henceforth the basic dyes of this series were considered merely as salts of the extremely unstable quinonoid colored ammonium base, the desmotropic colorless salts (IV) still remaining unknown. Similar considerations were extended to cover also the constitution of the acid, hydroxylated dyes.

(3) It was realized that triphenylcarbinol itself, devoid of either basic or acid auxochrome groups, gives on combination with some acids, as halogen acids, colorless ester-like compounds of benzenoid constitution (V), as might normally be expected of tertiary alcohols; on combination, however, with other acids, as sulfuric acid, it was found that intensely colored compounds are produced possessing at the same time salt-like nature. Here again it was sought to explain this strikingly divergent behavior by assuming the presence of the chromophor quinonoid nucleus in the colored derivatives<sup>2</sup> (VI), *i. e.*, by considering these salt-like substances as the salts of the quinocarbonium base, which is, of course, the hypothetical desmotope of the carbinol itself. Although the quinonoid

<sup>1</sup> Hantzsch and Kalb, *Ber.*, **32**, 3109 (1899); Hantzsch and Ostwald, *Ibid.*, **33**, 278 (1900).

constitution of the sulfate received substantial corroboration of experimental nature, nonetheless there still lacked for the firm basis of the tautomeric conception in this group a single instance of the actual existence of a desmotropic pair of carbinols, one colored and the other colorless, or a single desmotropic pair of strictly isomeric derivatives, *i. e.*, two chlorides or two sulfates. Evidence of the possible existence of two forms of such derivatives was finally obtained in the case of the chlorides<sup>1</sup> themselves. When dissolved in liquid sulfur dioxide triarylcarbinols were found to give rise to colored solutions and to show a totally different chemical behavior from that when in any other solvent and when at the same time colorless. Their peculiar behavior when in this solvent was shown to be, by diverse experimental evidence, totally consistent with, and to be explainable only on the assumption that the colored modification possesses the quinoid constitution, and is in mobile equilibrium with the benzenoid modification. The isolation, however, of the colored halides in the solid state proved impossible, for on evaporation of the sulfur dioxide the equilibrium shifts wholly in favor of the benzenoid modification.

(4) The indisputable and direct evidence for the correctness of the tautomeric view was at last obtained in the shape of the two desmotropic forms of a carbinol. It has been found that parahydroxytriphenylcarbinol is capable of existing in both the colorless and the colored modifications.<sup>2</sup> The two forms were isolated in crystalline solid state and to these carbinols have been assigned the structures (VII) and (VIII).

Analogy alone should be sufficient to justify the structure assigned to the colored modification, analogy with the colored chlorides described in the preceding paragraph, and also analogy with the colored fuchsone, the constitution of which could only be as indicated (IX). But, further, it has been shown that there exists a striking difference in the rate of dehydration on moderate heating of the two carbinols. The ease with which the colored modification, in contradistinction to the colorless carbinol, changes

<sup>1</sup> Gomberg, *Ber.*, **40**, 1846 (1907); *Ibid.*, **42**, 406 (1909).

<sup>2</sup> Gomberg, *THIS JOURNAL*, **35**, 1035 (1913).

through loss of water into fuchsone is compatible only with a quinonoid structure for the former, wherein the two hydroxyl groups are linked to one and the same carbon atom.

(5) The fifth and final period in the development of the tautomeric conception as applied to the triarylmethane derivatives remains still unattained. It has not as yet proven possible to prepare two desmotropic chlorides in solid crystalline state, or two sulfates. As a near approach to the realization of this may be considered the fact that while the triarylcarbinol chlorides are colorless, another set of analogous acid derivatives, the sulfates, are always colored. A still nearer approach to this realization are some of the results described in connection with the study of the arylxanthenols.<sup>1</sup> It has been shown that while some arylxanthenol chlorides are colorless, others although entirely analogous, are colored; and again, with the same xanthenol the chloride may be colorless while the bromide is colored. But, in the dyes, there still remains unattained the isolation of the true ammonium bases tautomeric with the colorless carbinols, or of the colorless salts tautomeric with the dyes themselves.

**Object of this Investigation.**—A single carbinol has been reported as existing in two desmotropic forms and it seemed desirable to extend this study to the various substituted triphenylcarbinols, having in view the effects on the tautomeric tendency which might be brought about by various groups in the benzene ring. Since the greatest effect would probably be brought about through substitution in the same ring containing the parahydroxyl group, we have for the present studied the carbinols substituted in this ring, namely, those positions ortho to the hydroxyl group. It has been found possible to extend the instances of isolation of the desmotropic forms through a number of substituted carbinols, and at the same time to gain some knowledge what groups enhance or diminish the specific influence of the para hydroxyl groups. Whether of the simple groups only the hydroxyl, and only in the para position, has this specific influence, is difficult to say at present, and this must be left open for further study.

## II. Substituted *p*-Hydroxytriphenylcarbinols.

Gomberg and Jickling<sup>2</sup> have lately reported a new method for the preparation of *p*-hydroxytriphenylcarbinol by the condensation of benzophenone chloride and phenol. They formulate the reaction as passing through several successive steps in virtue of various intramolecular rearrangements and they have been able to isolate the intermediate products formed:

<sup>1</sup> Gomberg and West, *THIS JOURNAL*, 34, 1529 (1912).

<sup>2</sup> *THIS JOURNAL*, 37, 2575 (1915).

Diphenoxydiphenylmethane,  $(C_6H_5)_2C(OC_6H_5)_2$

*p*-Hydroxytriphenylcarbinol,  $(C_6H_5)_2C(OH)(C_6H_4OH)$

Di-*p*-hydroxytetraphenylmethane,  $(C_6H_5)_2C(C_6H_4OH)_2$ .

We have now studied the condensations of benzophenone chloride with other phenols and have found that this reaction offers a very general method for the synthesis of *p*-hydroxytriphenylcarbinols. We have prepared the carbinols required for our work by this method rather than to use the methods described for this purpose in the literature, which are laborious, involving many steps and giving only meager yields. We have studied the action between benzophenone chloride and the following phenols: *o*-cresol, guaiacol, *o*-bromophenol, *o*-chlorophenol, and *o*-nitrophenol. With the exception of the nitro compound, we have been able to show that a reaction analogous to the first step, as formulated by Gomberg and Jickling, takes place in every case without the aid of a catalytic agent. The various substituted diphenoxydiphenylmethanes have been isolated and are, generally speaking, similar in character and stability to the diphenyl ether of benzophenone. Likewise, the condensation with *o*-cresol, and with guaiacol, proceeded easily through the second step to the formation of the substitutes *p*-hydroxytriphenylcarbinols. With the monobromo- and monochlorophenols it was found that under similar conditions the reaction stopped with the first step, and only the substituted diphenoxydiphenylmethanes could be isolated. It was found that upon addition of the smallest amount of sulfuric acid the reaction between the chloro- or bromophenol and benzophenone chloride proceeded much more vigorously than when the reaction depended upon the hydrochloric acid generated during the course of the condensation. A satisfactory rearrangement of the chloro- and bromophenoxy compounds was only effected when, besides the addition of a drop of sulfuric acid, the reaction mixture was heated for twelve hours at  $110^\circ$ , but this unfortunately brought about decomposition products which made the isolation of the carbinols difficult. Much better results were obtained by substituting aluminum chloride for the sulfuric acid as the condensing agent. In the presence of anhydrous aluminum chloride, using carbon disulfide as a solvent, the reaction between the bromophenol or chlorophenol and benzophenone chloride yielded the desired carbinols, and for our further study this method was employed.

On long standing or when the reaction is carried on at elevated temperatures, benzophenone chloride and phenol yield a tetraphenylated derivative. Under similar conditions we have been able to carry the condensation between the benzophenone chloride and *o*-cresol or guaiacol to analogous compounds.

As previously mentioned, the reaction between *o*-nitrophenol and benzophenone chloride did not proceed in the desired manner. On mixing these

two substances together and slightly warming there was only the slightest evolution of hydrochloric acid gas; with the addition of a drop of sulfuric acid this was only slightly increased. By heating on the water bath there were signs of a more vigorous reaction, but the final product was a charred mass and nothing could be isolated from it. The use of aluminum chloride and carbon disulfide did not yield the desired results. Recourse was finally had by carrying on the reaction between benzophenone chloride and *o*-nitrophenol in the presence of anhydrous aluminum chloride without the use of a solvent, and from this reaction the nitro-substituted carbinol for our work was obtained.

By brominating and by chlorinating the cresyl and guaiacyl carbinols we obtained carbinols substituted in both positions ortho to the para-hydroxyl group, and these also were studied as regards their tendency toward tautomerization. Similarly, the monobromo- and monochloro-carbinols were further brominated and chlorinated, respectively, and the dihalogenated carbinols thus resulting were in their turn investigated.

**The Desmotropic Modifications of Substituted *p*-Hydroxytriphenylcarbinols.**—The substitution of various groups in the position ortho to the hydroxyl group did not materially change the general characteristics of the carbinols from those of the *p*-hydroxytriphenylcarbinol itself. In every case save that of the nitro compound we were able to isolate two distinct forms, the colorless benzenoid (X), and the colored quinonoid (XI).

The colorless variety is best obtained by first dissolving the carbinol in normal alkali, precipitating with carbon dioxide and finally crystallizing from such solvents as benzene, ether or alcohol. The second crop of crystals in some cases shows a slight tinge of color, indicating that without doubt the solution contains both forms in equilibrium, but with a predominance of the colorless modification.

The quinonoid modification is always obtained by crystallizing the benzenoid variety from 60 to 70% acetic acid, and in some cases it is necessary to heat the solution for a considerable time to effect a complete change. If recrystallization takes place from more dilute acid, 30 to 40%, the colored modification separates out with less color, higher melting point, and is doubtless a mixture of the two modifications. If stronger acid is used there results in some cases the fuchsone, in others a carbinol acetate. On repeated recrystallization of the quinonoid desmotrope, even without previous treatment with alkali, from benzene,

alcohol, or ether, there is a marked tendency to the formation of the benzenoid variety. The quinonoid carbinols in nearly all instances possess a lower melting point than the corresponding benzenoid modifications.

Although the transformations of the benzenoid modification into the quinonoid take place readily in solution, the identical changes may be brought about to some extent without the use of solvents. With the application of heat the white modification becomes colored, the melting point drops, and eventually, with the loss of a molecule of water, the fuchson is formed, the rapidity of these various changes being determined by the temperature chosen.

The effect of light energy will also bring about the change from the colorless to the colored modification and, although here the effect, to be sure, is much slower, nevertheless with sufficient time and by occasional stirring in order to expose all of the material to sunlight or light from a mercury lamp, a complete change may be effected.<sup>1</sup>

We have assigned, in each case, the benzenoid structure to the white modifications and to the colored carbinols the quinonoid formulation. The benzenoid structure for the colorless carbinols requires no further explanation, it being in harmony with the generally accepted view as regards this class of compounds. Our justification for the quinonoid structure rests upon the analogy to the triaryl halides in the colored form, the relation to the fuchson, and, particularly, *upon the rate of dehydration under the influence of heat as compared with that of the benzenoid modification*. We have carried out all the dehydrations at a temperature where the transformation from the benzenoid to the quinonoid modification is slow as compared to the loss of water from the colored compound, the temperature in each individual case being also so chosen as to minimize the possible decomposition of the resulting fuchson. In most cases a temperature of 75° proved the most favorable for our purpose.

### III. Reaction between Benzophenone Chloride and *o*-Cresol.

As has been said, the reaction between phenol and benzophenone chloride was found to take place in several successive steps. Between the reaction of phenol and *o*-cresol with benzophenone chloride there is no striking difference. Products which are similar to those isolated with the phenol reaction have been prepared in the course of this work through the reaction of benzophenone chloride upon *o*-cresol. Through the use of a solvent, from which the hydrochloric acid gas generated in the reaction between *o*-cresol and benzophenone chloride may be expelled either by boiling or by the rapid passage of dried air, we have been able to prepare the substituted diphenylether of benzophenone. Without the use

<sup>1</sup> Gomberg, *THIS JOURNAL*, 35, 1039 (1913).

of a solvent the condensation proceeds through the second step, yielding 3-methyl-4-hydroxytriphenylcarbinol, and even through the third step, giving 3,3'-methyl-4,4'-hydroxytetraphenylmethane.

**2,2'-Methyldiphenoxydiphenylmethane**,  $(C_6H_5)_2C(OC_6H_4CH_3)_2$ .—To the warm solution of 24 g. (1 mol) of benzophenone chloride in 250 cc. of dry benzene are added gradually 27 g. (2.5 mol) of redistilled *o*-cresol. The flask is fitted with a reflux condenser and protected from the moisture of the air by a calcium chloride tube. The solution is gently heated on the water bath, and when no further acid fumes are given off, usually after three to four hours, the reaction may be considered to be at an end. The benzene is evaporated off under reduced pressure and to the yellow oil remaining a few cc. of alcohol are added. Any excess of *o*-cresol or benzophenone chloride that may be present goes into solution in alcohol while the ether separates out as a white solid partly crystalline. For purification it is recrystallized from hot alcohol, and it then melts at 142°. The yield is nearly quantitative. The cresoxy compound is characterized by its insolubility in the ordinary solvents. It is stable to steam distillation, is not soluble nor decomposed by alkalis, but acids decompose it to benzophenone and the *o*-cresol.

Calc. for  $C_{27}H_{24}O_2$ : C, 85.21; H, 6.36. Found: C, 85.23, H, 6.47.

**3 - Methyl - 4 - hydroxytriphenylcarbinol** (*o*-Cresyldiphenylcarbinol),

Zurbruggen<sup>1</sup> first prepared *o*-cresyldiphenylcarbinol through the condensation of benzilic acid with *o*-cresol and subsequent removal of the carbon dioxide from the resulting cresyldiphenylacetic acid by use of especially prepared 100% sulfuric acid. The preparation by this method is laborious and the yields are comparatively small. On the other hand, according to our method, an almost theoretical yield of the cresyldiphenylcarbinol is obtained.

24 g. (1 mol) of benzophenone chloride are mixed with 27 g. (2.5 mol) of redistilled *o*-cresol, the mixture is at first cooled, and then allowed to stand at room temperature for from two to four days, protected from the moisture of the air by a calcium chloride tube. After the addition of a little water, the mixture is steam distilled to remove the excess cresol. The residue, after steam distillation, is digested with warm normal alkali and the solution, after cooling, is filtered from benzophenone not carried over in the steam distillation. To remove all traces of benzophenone which may be held in suspension or in solution by the alkali, the solution is shaken with small amounts of ether, and the ether dissolved in the

<sup>1</sup> *Ber.*, 36, 3558 (1903).

alkaline solution of the carbinol is removed from the solution by passage of a brisk stream of air. To the alkaline solution small amounts of solid sodium chloride are gradually added; on standing the sodium salt of the carbinol crystallizes out in long needles with almost no color. These are filtered, washed with a little water, redissolved in warm water, and the free carbinol is precipitated by passing carbon dioxide into the alkaline solution. On standing, the oily carbinol solidifies and is then filtered and air-dried.

Further purification of the carbinol is best accomplished by converting it into the insoluble acetate (see below) and then regenerating the carbinol. The crude carbinol is dissolved in a small amount of hot glacial acetic acid. On cooling and stirring the entire mass becomes suddenly solid, and the beautiful red crystals of the acetate thus formed may be filtered from the acid, while any tetraphenylmethane derivative that may possibly be present remains in solution in the acid. The red crystals of the carbinol acetate lose their acetic acid when allowed to stand exposed to the air. The resulting fuchsone is now hydrolyzed back to the carbinol by gently warming it with dilute alkalis and some alcohol or acetone, and is then reprecipitated from the solution with carbon dioxide. Further treatment of this carbinol is conditioned upon which of the two desmotropes it is desired to obtain.

**The Quinonoid and Benzenoid Desmotropes.**—On recrystallization of the purified carbinol from 60% acetic, the quinonoid modification of the carbinol is obtained pure, melting at 108–109° and colored a beautiful yellow. Bistrzycki and Zurbriggen reported that their carbinol melted at 108–109°, was yellow, and on recrystallization the melting point was raised. As a solvent they used acetic acid of 50% strength, and we have also found that with this strength acid the tendency to produce the colorless variety is only hindered by long heating. When the carbinol was precipitated from its alkaline solution by means of dilute acetic acid, Bistrzycki and Herbst<sup>1</sup> obtained a compound identical in composition with the original carbinol yet which, on recrystallization from benzene, was colorless and melted at 148–149°. We have been able to prepare this white variety of the carbinol, namely the benzenoid desmotope, by taking the product precipitated from alkaline solution by carbon dioxide and, after drying, recrystallizing it from alcohol, benzene, or ether and petroleum ether. In every case we were able to obtain a compound identical in composition to the colored carbinol, perfectly white and melting at 148–149°, although often the second batch of crystals showed signs of the colored modification. By dissolving the colorless modification in 60% acetic acid and warming for a short time, the colored carbinol, melting at 108–109°, is obtained. If acid of less strength is used the melting

<sup>1</sup> *Ber.*, 36, 3566 (1903).

point is lowered to 120–130° and the result is a mixture of the two desmotropes possessing a light yellow color. On the other hand, by repeated recrystallization from alcohol or benzene the colored carbinol gradually changes to the white, higher melting, benzenoid desmrope. On long exposure in a quartz dish to the rays of the sun, the white modification becomes yellow, but a similar change is noticed in the course of a few hours if the same compound is warmed to 60°.

Calc. for  $C_{26}H_{18}O_2$ : C, 82.72; H, 6.25. Found: Quinonoid desmrope, C, 82.56; H, 6.18; Benzenoid desmrope, C, 82.7; H, 6.24.

**Dehydration of the Two Forms of the *o*-Cresyldiphenylcarbinol.**—Equal amounts of the two desmotropes were heated at the same time in an especially constructed glycerol bath which allowed a very accurate control of the temperature. This bath consisted of a rectangular copper tank measuring  $9 \times 6 \times 4$  inches, through the entire length of which extended two copper tubes. When the bath was filled with glycerol and heated, by means of a Bunsen burner beneath, a thermometer which was immersed through an opening in the top into the glycerol showed less than a degree change of temperature during periods extending over several weeks. One gram of each desmrope was placed in a porcelain boat about five inches long, the boats placed each in one of the separate tubes, and a slow stream of carefully purified and dried air was passed throughout the period of heating. The rate of dehydration, *i. e.*, the loss of water, was carefully noted at different intervals. While the colored desmrope loses water rapidly, the white modification loses it slowly, *in proportion as it is being transformed under the influence of heat energy into the quinonoid desmrope*. In the tables below showing the rates of dehydration the time

Fig. 1.

represents the different intervals of heating, while the percentages given show the total loss of weight in per cent. at the end of that interval. On longer heating the further loss in either case was on the average of 1 mg. per day, which, as will be shown, is due to the decomposition of the fuchson itself.

Temperature.	Time.	Quinonoid.	Benzenoid.
70°	24 hrs.	4.86%	0.47%
70°	24 hrs.	6.12%	1.31%
70°	24 hrs.	6.24%	1.81%
70°	24 hrs.	6.38%	2.85%
70°	70 hrs.	6.42%	6.30%

Calculated loss for one molecule of water is 6.25%.

**Decomposition of Fuchsones on Heating.**—When the dehydration of various carbinols was undertaken at temperatures ranging from 100°

to 150°, it was found that there resulted always a loss considerably more than that calculated for one molecule of water. We have been able to show that at temperatures from 75° and up appreciable decomposition of the fuchsone may take place with the production of small amounts of benzoquinone or its homologs, which are quite volatile, and the loss in weight, on heating the carbinols, in excess of that calculated for one molecule of water is thus accounted for. We have been able to isolate and completely identify benzoquinone resulting in this manner from *p*-hydroxytriphenylcarbinol; tolylquinone, from *o*-cresyldiphenylcarbinol; and methoxyquinone, from 2-methoxy-*p*-hydroxytriphenylcarbinol.

In view of this fact care has to be exercised to select for the dehydration experiments such a temperature that this decomposition would be a minimum, and our results justify the selection of 75°. The facts just described clear up a discrepancy in the observations made by Gomberg, on the one hand, and by Baeyer on the other. Gomberg<sup>1</sup> reported that by the action of silver sulfate on *p*-bromotriphenylchlormethane a *p*-quinone sulfate is produced and that this on hydrolysis yields fuchsone. The latter was not isolated at that time but its presence was inferred from several reasons, among them, by the distinct odor resembling that of benzoquinone. Baeyer<sup>2</sup> disputed the correctness of this observation claiming that the fuchsone has no odor. The fact that fuchsone on gentle heating does give rise to benzoquinone explains the discrepancy in the two observations. We have now verified that *freshly prepared fuchsone* is without odor, but when kept in a closed bottle, even if only at room temperature, in the course of several days it suffers sufficient autooxidation to give rise to an unmistakable trace of benzoquinone.

When either of the two modifications of the *o*-cresyldiphenylcarbinol are dehydrated, either by heat or by glacial acetic acid, there results the diphenyl-2-methylquinomethane. If the dehydration of the solid forms of the carbinol takes place at a low temperature, this transformation takes place without fusion of the material, and the resulting fuchsone melts at 173–175°. On recrystallization from benzene, it is obtained as deep red crystals melting at 176°, as described by Bistrzycki and Zurbruggen. It is very soluble in alcohol, ether or acetic acid.

Calc. for  $C_{20}H_{16}O$ : C, 88.19; H, 5.927. Found: C, 88.02; H, 5.935.

**Diphenyl-2-methylquinomethane Acetate.**—When either form of the carbinol is dissolved in hot glacial acetic acid and the solution afterwards cooled and stirred the entire mass becomes solid. The deep red crystals

<sup>1</sup> *Ber.*, 40, 1853 (1907).

<sup>2</sup> *Ibid.*, 40, 3086 (1907).

resulting may be filtered off, washed with petroleum ether, dried between filter papers and used for analysis. The same product results if the carbinols are dissolved in the cold and the acid solution is allowed to stand, when the acetate resulting separates out, owing to its lesser solubility. On heating to  $75^{\circ}$  or on exposure to air the acetate loses the acid, leaving the fuchson. The loss in weight can be checked by passing the acid evolved into a standard alkali solution.

Calc. for  $C_{20}H_{16}O + C_2H_4O_2$ :  $C_2H_4O_2$ , 18.08. Found:  $C_2H_4O_2$ , 18.07, 18.13.

The influence of the *p*-hydroxyl group in inducing tautomerization of this cresyl carbinol to the quinoid state is well brought out by the existence of this colored acetate. Triphenylcarbinol itself also gives an acetate but that one is perfectly white. On the other hand, *p*-hydroxytriphenylcarbinol, when dissolved in sufficient cold glacial acetic acid to make a saturated solution, deposits on standing the acetate intensely colored. Still better results are obtained by starting with the cold saturated solution of the diphenylfuchson. The reaction in this case with acetic acid is not unlike that with hydrochloric acid.

**3,3'-Methyl-4,4'-hydroxytetraphenylmethane**,  $(C_6H_5)_2C(C_6H_3CH_3 \cdot OH)_2$ .—If the reaction mixture between benzophenone chloride and *o*-cresol is allowed to stand several weeks, or if the reaction is carried on at temperatures slightly elevated, the condensation goes to the final step and from the product that results one can isolate appreciable amounts of the substituted tetraphenylmethane.

To 14 g. of benzophenone chloride were added 16 g. of distilled cresol and the mixture was warmed on the water bath for three days. The reaction mixture was then steam distilled to remove the excess of cresol, taken up in normal alkali, the latter shaken with ether to remove the benzophenone, and the product thrown down by the addition of dilute acetic acid to the alkaline solution. On crystallization from dilute acetic acid, it separated out as white crystals melting at  $183^{\circ}$ , which, on recrystallization from benzene, alcohol, acetic acid or toluene, melt at  $190^{\circ}$ . Unlike di-*p*-hydroxytetraphenylmethane, this compound is extremely soluble.

Calc. for  $C_{28}H_{24}O_2$ : C, 85.22; H, 6.36. Found: C, 84.82; H, 6.56.

#### Attempts to Isolate the Free Radical.

**3-Methyl-*p*-carboethoxytriphenylcarbinol**,  $C_2H_5O.CO.OC_6H_3CH_3 \cdot (C_6H_5)_2COH$ .—As the carbinol chloride itself could not be expected to give the free radical the hydroxyl group was protected by the carboethoxy

cresylidphenylcarbinol takes place in either acetic acid or chloroform. For this purpose the carbinol was dissolved in glacial acetic acid and to this solution was added gradually a large excess of bromine dissolved in the same solvent. After standing at room temperature with occasional shaking, it was warmed on the water bath for a few hours. On cooling slowly there separated out deep red crystals. These were shown, by analysis, to contain bromine substituted in the benzene ring and removable only by drastic treatment, as fusion with sodium peroxide; also bromine which could be easily hydrolyzed off, and in addition bromine that could be titrated by sodium thiosulfate. There can be no doubt that this red compound is a perbromide of a quinonoid-carbinol bromide with apparently three atoms of perbromine, as shown by titration with thiosulfate. Often on cooling too rapidly there separated out along with the crystals of the perbromide a black oil, but this can be put back into solution on application of heat and additional acid.

To obtain the bromocresylcarbinol from this perbromide, two methods may be employed. The red crystals are boiled with a large amount of water; or the perbromide may be taken up in ether, washed with a strong solution of sodium bisulfite in order to remove the bromine, and, after drying the ether solution, the carbinol may be precipitated by addition of petroleum ether. The product resulting in either case is likely to contain a considerable amount of the brominated fuchson. It is, therefore, advisable to redissolve the whole in warm alkali in order to hydrolyze the fuchson, and the carbinol is then precipitated out by addition of dilute acid or by passing carbon dioxide into the solution. On recrystallization from acetic acid 60%, the carbinol is colored red and melts at 138–139°. It represents the quinonoid modification. As was shown to be the case with the *o*-cresylcarbinol, more dilute acid brings about some loss of color in the carbinol and a variable rise in melting point, owing to the formation of a mixture of the

Fig. 2.

#### DEHYDRATION OF THE TWO MODIFICATIONS OF THE CARBINOLS.

Temperature.	Time of heating.	Quinonoid.	Benzenoid.
75°	3 hrs.	2.4	No loss
75°	22 hrs.	4.54	No loss
75°	24 hrs.	4.75	No loss
75°	24 hrs.	4.90	No loss
90°	48 hrs.	4.97	1.00
105°	120 hrs.	5.40	5.30
105°	48 hrs.	5.40	5.45

Calculated loss for one molecule of water is 4.89%.

To obtain the colorless desmotrope, the carbinol is dissolved in normal alkali, precipitated by means of carbon dioxide, and the product obtained filtered, dried, and recrystallized from benzene or ether and petroleum ether. On repeated recrystallization it is obtained entirely white and melts at  $145^{\circ}$ . The manner of the mutual transformation between these two modifications does not differ greatly from that observed and previously cited in the case of the *o*-cresylcarbinols. On the whole, however, the presence of the bromine in the nucleus imparts to the benzenoid desmotrope somewhat greater stability in the sense that it shows a lesser tendency to tautomerize to the quinonoid form than the non-brominated carbinol, and may be kept colorless for a longer time than the latter.

**Diphenyl-2-methyl-6-bromo-quinomethane**,  $(C_6H_5)_2C : C_6H_2BrCH_3 : O$ . —Dehydration of the carbinol in either desmotropic modification can be carried on at such a temperature that no fusion occurs and yet there results the brominated fuchsone compound. This, on recrystallization from benzene, is orange-red and melts at  $202^{\circ}$ . It dissolves in the ordinary organic solvents very easily but is insoluble in petroleum ether.

Calc. for  $C_{20}H_{18}OBr$ : Br, 22.72. Found: Br, 23.3.

**3 - Methyl - 5 - chloro - *p* - hydroxytriphenylcarbinol**,  $(C_6H_5)_2C(OH)CH_3$  —

lowing procedure was adopted for the chlorination of the *o*-cresylcarbinol: To 16 g. (1 mol) of cresyldiphenylcarbinol suspended in carbon tetrachloride was added chlorine (1 mol) previously dissolved also in carbon tetrachloride. As the reaction proceeds the suspended carbinol goes into solution with evolution of hydrochloric acid gas. Towards the end of the reaction the solution was warmed on the water bath, and then concentrated to a small bulk. On standing there separated out the chlorofuchsone, an orange-colored compound. To hydrolyze it to the carbinol, it was found necessary to warm the fuchsone for a long time with alkali. The carbinol was then precipitated from the alkaline solution by means of carbon dioxide, dried and recrystallized from 60% acetic acid. Unless heated for some time with acetic acid of this strength, quinoidation is likely to be incomplete. The quinonoid desmotrope thus obtained possesses a yellow color and melts at  $133^{\circ}$ . If recrystallization of the quinonoid carbinol takes place from alcohol, benzene or ether, the carbinol is partially changed into the colorless desmotrope. It is, however, difficult to obtain an entirely white compound

in this way except by repeated recrystallizations. If, however, the colored carbinol is first dissolved in normal alkali and then, after reprecipitation with carbon dioxide, is dissolved in any of the above-mentioned solvents, it appears as an entirely white compound, melting at  $149^{\circ}$ .

The white modification of the chlorocresylcarbinol shows a stability far greater than any of the colorless modifications so far mentioned. This stability shows itself in the dehydration experiment, the white carbinol changing but very slowly into the quinonoid carbinol under the influence of heat; furthermore, even on recrystallization from 60% acetic acid the colorless form persists in crystallizing out unless the solution is previously warmed for some time.

DEHYDRATION OF THE TWO MODIFICATIONS OF THE CARBINOL. TEMP.  $75^{\circ}$ .

Time of heating.	Quinonoid.	Benzenoid.	Time of heating.	Quinonoid.	Benzenoid.
$1\frac{1}{2}$ hrs.	0.71%	No loss	24 hrs.	5.6%	0.32%
4 hrs.	1.53%	No loss	48 hrs.	5.6%	0.62%
18 hrs.	3.1%	0.12%	72 hrs.	5.7%	1.72%
24 hrs.	4.3%	0.2%	after 12 days	5.7%	5.62%

Theoretical loss due to one molecule of water is 5.54%.

Fig. 3.

**Diphenyl-2-methyl-6-chloroquinomethane.**—This fuchstone, which results from the dehydration of either modification of the chlorocresylcarbinol, melts at  $197^{\circ}$  and is far more stable towards heat than most of the other analogs studied. It is easily soluble in most of the usual organic solvents. It is hydrolyzed with difficulty to the carbinol by alkali alone, but if a slight amount of alcohol is added to the alkali solution the carbinol is easily formed and passes into solution.

Calc. for  $C_{20}H_{18}OCl$ : Cl, 11.58. Found: Cl, 11.42.

#### IV. Reaction between Benzophenone Chloride and Guaiacol.

The reaction between benzophenone chloride and guaiacol follows the same course as the condensation of the keto-chloride with either

phenol or *o*-cresol. We have been able to so arrange the conditions as to obtain similar products to those isolated in these previously mentioned cases.

**2,2'-Methoxydiphenoxy-diphenylmethane**,  $(C_6H_5)_2C(OC_6H_4OCH_3)_2$ .—To the warmed solution of 24 g. (1 mol) of benzophenone chloride in benzene are added 30 g. (2.5 mol) of distilled guaiacol and the mixture heated on the water bath until the evolution of hydrochloric acid ceases. On evaporation of the excess of benzene a yellow oil separates out which on addition of small amounts of alcohol becomes solid and partly crystalline. This is filtered and recrystallized from hot alcohol or ether, in either of which it is only slightly soluble. When obtained in this manner it is a white compound melting at  $189^\circ$ . Like its analogs already mentioned, it stands steam distillation, is insoluble in alkalis, but acids decompose it into benzophenone and guaiacol.

Calc. for  $C_{27}H_{24}O_4$ : C, 78.6; H, 5.87. Found: C, 78.15; H, 5.90.

**3-Methoxy-*p*-hydroxytriphenylcarbinol**,

phenone chloride and guaiacol proceeds in absence of a solvent there results the substituted *p*-hydroxytriphenylcarbinol. This reaction takes place, however, much more slowly than in the case of phenol or *o*-cresol.

In a long-necked round-bottom flask 24 g. (1 mol) of benzophenone chloride are mixed with 30 g. (2.5 mol) of redistilled guaiacol and allowed to stand at room temperature for from two to three weeks. No attempt at cooling is necessary, since the reaction proceeds very slowly and apparently without generation of much heat. The manipulation for isolation of the carbinol differs but little from that employed in the isolation of the *o*-cresol carbinol. After steam distillation to remove the excess of guaiacol the product remains as a yellow oil which solidifies even while warm. This is digested with normal alkali, the solution is cooled and filtered, and the carbinol precipitated by means of carbon dioxide. On standing, this precipitate becomes solid and may be filtered, dried, and recrystallized from benzene. There is probably only the slightest trace of the tetraphenylated derivative present and this remains in solution while the triphenylcarbinol separates out from the hot benzene on slight cooling, being, unlike its analogs, but slightly soluble in this solvent. When obtained in this way the guaiacol compound is entirely white, and melts at  $159^\circ$ . It dissolves in 60% acetic acid with the production of color and after slight warming crystallizes out in the quinonoid modifica-

tion, melting at  $147^{\circ}$ , and is colored brown. The effects of heat, light, and solvents do not differ in general from those in the case of the carbinols

previously mentioned.

Calc. for  $C_{20}H_{18}O_4$ : C, 78.38%; H, 5.93%. Found (colored desmotrope): 77.92 and 5.72; (white desmotrope): 78.11 and 5.89.

#### DEHYDRATION OF THE TWO FORMS OF THE CARBINOL.

Fig. 4.

Temperature.	Time of heating.	Quinonoid.	Benzenoid.
$75^{\circ}$	15 min.	0.32%	No loss
$75^{\circ}$	15 min.	1.97%	No loss
$75^{\circ}$	30 min.	2.94%	0.10%
$75^{\circ}$	30 min.	3.94%	0.12%
$75^{\circ}$	45 min.	5.39%	0.15%
$75^{\circ}$	12 hrs.	....	0.39%
$75^{\circ}$	18 hrs.	....	1.46%
$75^{\circ}$	46 hrs.	....	3.27%
$75^{\circ}$	78 hrs.	....	5.37%

The loss calculated for 1 mol. of water is 5.24%.

**Diphenyl-2-methoxy-quinomethane**,  $(C_6H_5)_2C : C_6H_3OCH_3 : O$ .—The fuchson which results from the dehydration of either form of the guaiacyl carbinol when recrystallized from benzene melts at  $183^{\circ}$ . It is very soluble in ordinary solvents, is with difficulty hydrolyzed to the carbinol by alkali, but more easily with the addition of slight amounts of alcohol. Of all the fuchsones studied we have found none of them as unstable towards heat as the guaiacyl fuchson. We have been able to isolate the methoxybenzoquinone which results from this decomposition and have found that its melting point is  $145^{\circ}$ , as reported recently by Moore,<sup>1</sup> and not  $140^{\circ}$ , as has appeared in the older literature.

**2,2'-Methoxydi-*p*-hydroxydiphenylmethane**,  $(C_6H_5)_2C(C_6H_3OCH_3OH)_2$ .—We have been able to obtain this compound in small amounts by carrying on the reaction between benzophenone chloride and guaiacol at elevated temperatures.

12 g. of benzophenone chloride and 15 g. of guaiacol were mixed and allowed to react for a week at a temperature of  $60^{\circ}$  to  $65^{\circ}$ . In working up the reaction mixture in the usual way, there is precipitated from the acetic acid solution on the addition of water small amounts of a high melting compound. It is characterized by its solubility in benzene which renders its separation from the corresponding triphenylcarbinol derivative very simple. On heating it softens at  $200^{\circ}$  and melts at  $208^{\circ}$ .

Calc. for  $C_{27}H_{24}O_4$ : C, 78.6; H, 5.87. Found: C, 78.73; H, 5.56.

**3 - Methoxy - 5 - bromo - *p* - hydroxytriphenylcarbinol**,

<sup>1</sup> *J. Chem. Soc.*, 99, 1045 (1911).

The reaction mixture is warmed on the water bath and finally concentrated to a small bulk. On cooling there separates out the brominated guaiacyl fuchson. The fuchson is hydrolyzed with normal alkali and the free carbinol is obtained in the benzenoid state by precipitation from the alkaline solution by means of carbon dioxide. On recrystallization from ether and petroleum ether it melts at  $156^{\circ}$  and is entirely white.

The quinonoid modification of the carbinol is obtained when the colorless carbinol is warmed with  $60^{\circ}$  acetic acid, and on crystallizing from this solvent it is an orange colored substance melting at  $151^{\circ}$ .

#### DEHYDRATION OF THE TWO MODIFICATIONS OF THE CARBINOL.

Temp.	Time.	Quinonoid.	Benzenoid.	Temp.	Time.	Quinonoid	Benzenoid.
$75^{\circ}$	14 hrs.	1.48	0.15	$75^{\circ}$	6 days	4.65	2.22

$75^{\circ}$	3 days	4.1	0.85	$95^{\circ}$	2 days	....	4.85

Theoretical loss for one molecule of water is 5.87%.

Fig. 5.

**Diphenyl-2-methoxy-6-bromoquinomethane.** — This bromoguaiacyl-fuchson is obtained by dehydration of either modification of the carbinol. It is stable at  $75^{\circ}$ , is soluble in benzene and acetic acid, and, when crystallized from either of these solvents, is a dark red compound, melting at  $232^{\circ}$ .

Calc. for  $C_{26}H_{18}O_2Br$ : Br, 21.77. Found: Br, 22.22.

3 - Methoxy - 5 - chloro - *p* - hydroxytriphenylcarbinol,

carbinol were suspended in a small amount of carbon tetrachloride and to this was gradually added the calculated amount (1 mol) of chlorine in solution in carbon tetrachloride. As the reaction proceeds the guaiacyl carbinol goes into solution and there is an evolution of hydrochloric acid gas. Towards the end of the reaction the mixture is warmed on the water bath. The carbon tetrachloride is evaporated and the fuchsonone thus obtained recrystallized from benzene. On long heating, this goes into solution in normal alkali and the chlorinated guaiacyl carbinol is obtained on reprecipitation by means of carbon dioxide. It is then recrystallized from 60% acetic acid, and the quinonoid modification is thus obtained. It is orange colored and melts at 159–161°. It dissolves in alcohol, benzene, or ether, the solution is only slightly colored, and on recrystallization from these solvents there is a marked rise in the melting point of the carbinol accompanied by loss of most of the color. The colorless modification is, however, best obtained by reprecipitation of the carbinol from its alkaline solution with carbon dioxide, and subsequent recrystallization from ether by addition of petroleum ether. When obtained in this manner, it melts at 166–168° and is perfectly white.

DEHYDRATION OF THE TWO MODIFICATIONS OF THE CARBINOL.

Theoretical loss calculated for one molecule of water is 5.26%.

Fig. 6.

**Diphenyl-2-methoxy-6-chloroquinomethane.**—The chloroguaiacylfuchsonone results from the dehydration of either modification of the carbinol.

It remains unaffected when heated for a long period at  $75^{\circ}$ , is soluble in hot benzene, in both these respects differing from the unchlorinated guaiacyl fuchson. It melts at  $227^{\circ}$  and on hydrolysis with alkali yields the carbinol.

Calc. for  $C_{20}H_{18}O_2Cl$ : Cl, 10.98. Found: Cl, 11.01.

### V. Reaction between Benzophenone Chloride and *o*-Bromophenol.

**2,2'-Bromodiphenoxydiphenylmethane**,  $(C_6H_5)_2C(OC_6H_4Br)_2$ .—6 g. of benzophenone chloride were mixed with 7 g. of *o*-bromophenol, which had been prepared from *o*-amidophenol by Sandmeyer's reaction. The reaction mixture was allowed to stand at room temperature for several days, no cooling being necessary. During this interval hydrochloric acid was continually given off. The excess of bromophenol was steam distilled, the product digested with normal alkali, but no material soluble in alkali could be isolated, *i. e.*, the condensation under these conditions did not yield any triarylcarbinol. On cooling, the yellow oil solidified and it was found to consist mostly of benzophenone and some of the diphenoxyether, the two being separated from each other by the insolubility of the latter in alcohol. On recrystallization from hot alcohol the ether melts at  $184$ – $185^{\circ}$ . The theoretical yield of this same product may be obtained by carrying on the reaction between benzophenone chloride and *o*-bromophenol in benzene solution and at a temperature sufficient to expel all the hydrochloric acid formed in the reaction.

Calc. for  $C_{23}H_{18}O_2Br_2$ : Br, 31.37. Found: Br, 31.82.

$(C_6H_5)_2C = \text{Cyclohexane ring with Br and OH}$ .—The fact that the condensation of benzophenone chloride with *o*-bromophenol under the usual conditions, fails to proceed beyond the first step, led us to study more fully the means whereby the phenoxy derivatives may be transformed into the corresponding triphenylcarbinols. A series of experiments on diphenoxydiphenylmethane has shown that this ether gives rise to the carbinol not only under the influence of hydrochloric acid but also when heated in the presence of a very small amount of sulfuric acid. However, when applied to the bromophenoxyether, even this treatment failed to produce more than only a small amount of the carbinol accompanied by a large amount of decomposition products. Nor was the result improved by adding sulfuric acid to the mixture of benzophenone chloride and *o*-bromophenol.<sup>1</sup> We have finally been able to prepare the desired carbinol

<sup>1</sup> Sachs and Thonet, *Ber.*, 37, 3329 (1904).

by use of these same materials in the presence of anhydrous aluminum chloride in carbon disulfide solution at ordinary temperatures, thus avoiding the decomposition products obtained in the other case.

The procedure used was as follows: 24 g. (1 mol) of benzophenone chloride are dissolved in carbon disulfide and the containing flask surrounded by ice-water. Alternatively there are added small amounts of *o*-bromophenol and finely powdered aluminum chloride until 1.2 mols of each have been added. After the reaction has subsided the mixture is allowed to warm up to room temperature and finally warmed on the water bath. After the evolution of hydrochloric acid gas has ceased the product is cooled and decomposed in the usual manner. The product which separates out as a thick oil is then subjected to steam distillation in order to remove the excess of bromophenol and the product remaining digested with normal alkali. From the filtered solution the sodium salt of the carbinol is precipitated through the addition of solid sodium chloride. The sodium salt is filtered, washed with small amounts of water, redissolved in warm water and the carbinol precipitated by means of carbon dioxide. On standing, the precipitate becomes solid, and is then filtered, dried, and recrystallized from a small amount of carbon tetrachloride. The carbinol resulting is slightly yellow in color, melts at 107–109°, and is entirely white when further recrystallized from ether and petroleum ether. It then melts at 109°.

The colored modification is obtained when acetic acid 60% is used as a solvent. When recrystallized from this solvent, the carbinol is orange in color, and the melting point is 104.5–105°.

That the constitution of this carbinol is that of a *p*-hydroxy compound and not that of the isomeric *p*-bromocarbinol, the production of which is not at all excluded by the process of preparation which has been employed, is proven by the following: On brominating our monobromo compound we get a dibromo compound which is entirely identical with the diphenyl-3-5-dibromo-4-hydroxycarbinol, described by Auwers and Schröten,<sup>1</sup> and the constitution of which can be no other than as given below.

Calc. for  $C_{19}H_{15}O_2Br$ : Br, 22.51. Found: Br, 23.01.

**Dehydration of the Two Modifications of the Carbinol.**—Although there is but little variance in the melting points of the two modifications of the bromophenolcarbinols and although the transformation of the white compound to the colored modifications under the influence of heat takes place comparatively easily, yet the difference in rates of dehydration points unmistakably to a difference in structure.

Diphenyl - 2 - bromoquinome -  
thane,  $(C_6H_5)_2C : C_6H_4Br : O$ . —

The product remaining from the dehydration of either form of the bromocarinol melts at 140° when recrystallized from benzene. This fuchsone is characterized by its low melting point, for all other fuchsones studied melt well over 160°.

3,5 - Dibromo - *p* - hydroxytriphenylcarbinol,

—This carbinol can be prepared, as has

been mentioned above, by brominating monobromo-*p*-hydroxytriphenylcarbinol. The more preferable method, however, is to brominate directly *p*-hydroxytriphenylcarbinol. The identity of the dibromides obtained by these two methods proves that the constitution assigned by us to the monobromocarinol as that of *p*-hydroxycarinol is correct.

Both Bistrzycki<sup>1</sup> and Auwers<sup>2</sup> have worked with the dibromocarinol, have recrystallized it from various solvents, but have failed to notice the existence of it in the two desmotropic forms.

The procedure for the purification of these compounds is as follows: *p*-Hydroxytriphenylcarbinol in acetic acid or in carbon tetrachloride is brominated with the required amount of bromine. The crude solid product is boiled with a small amount of glacial acetic acid. On cooling the insoluble dark orange-red dibromofuchsone crystallizes out, while any unbrominated carbinol remains in solution. The fuchsone is now hydrolyzed to the carbinol by gentle warming with dilute alkali and alcohol,

<sup>1</sup> Bistrzycki and Herbst, *Ber.*, 35, 3133 (1902).

<sup>2</sup> Auwers and Schröter, *Ibid.*, 36, 3237 (1903).

and the carbinol is precipitated by means of a stream of carbon dioxide or with very dilute acetic acid.

In order to obtain the benzenoid desmotrope the carbinol is recrystallized from benzene or from carbon tetrachloride, from which solvents it separated, however, with solvent of crystallization in each case. The crystals from benzene contain one-half molecule of solvent of crystallization, and this is held with considerable tenacity. Samples which have been kept in a desiccator for two weeks still contained about 8% of benzene, while the amount calculated for one-half molecule is 8.24%. The benzene, however, can be driven off at elevated temperatures, about 70°, but the carbinol acquires on this treatment a slight tinge of color. For our dehydration experiments, the carbinol freed from benzene was further recrystallized from ether and petroleum ether.

The preparation of the quinonoid desmotrope requires some care. The carbinol as obtained on the addition of dilute acid to its alkaline solution, is digested while still moist with 80% acetic acid, the filtered solution is gently warmed, and to it hot water is gradually added until the strength of the acid is reduced to about 60%. On cooling the quinonoid modification separates out in red crystals.

Although the two desmotropes differ strictly in their appearance, they both melt at about the same temperature. The purest benzenoid desmotrope melts at 138°, but in most instances the fusion point is found to be 134–136°, and this is the temperature at which the quinonoid modification melts. The colorless carbinol begins to turn quite red at about 90° and it is probable that the benzenoid desmotrope is almost completely converted into the quinonoid desmotrope before the fusion point is reached, and hence the identity of the melting points.

The two desmotropes may be differentiated from each other not only by their difference in color but also by their respective rates of dehydration on heating, as is the case with the pairs of tautomers of the other carbinols described in this paper. In the following experiment we employed, in obtaining the first set of curves, a sample of the benzenoid carbinol which has been obtained from its alkaline solution by treatment with carbon dioxide, washing thoroughly the precipitate and drying in a vacuum desiccator for two weeks. The quinonoid desmotrope employed was the crystalline compound ground to a powder in a mortar. Although the colorless compound was in a much finer state of division, yet the dehydration was slower than that of the colored. It is interesting to note the sudden breaks in the curves with the changes of temperature on heating. In the second experiment both desmotropes employed were crystalline and were reduced to about the same degree of fineness in a mortar and were kept at a constant temperature.

## VI. Reaction between Benzophenone Chloride and *o*-Chlorophenol.

In the reaction between *o*-chlorophenol and benzophenone chloride the same difficulties and limitations were encountered as in the condensation with bromophenol. The chlorinated phenoxy compound was readily produced, but we were unable to effect its rearrangement except under conditions which rendered the isolation of the triarylcarbinol difficult. Again, as with the bromophenol, we had recourse in the use of anhydrous aluminum chloride.

**Preparation of *o*-Chlorophenol.**—By direct chlorination of phenol there results mostly the *p*-chlorinated compound with relatively small amount of the *o*-chlorophenol. We have tried the various methods reported in the literature, and have found that the method reported by Lossen,<sup>1</sup> chlorinating in carbon tetrachloride solution by means of chlorine dissolved in this same solvent, yielded the best results, 100 g. of phenol yielding as much as 35 g. of the desired compound. For separation from the *p*-chlorophenol, as well as from the unchanged phenol, the method employed by Holleman<sup>2</sup> was used. The reaction mixture is suspended in potassium carbonate solution and shaken with ether, whereby the unchanged phenol is removed by the ether while the chlorophenols remain in the alkaline solution. This is now acidified, the liberated chlorophenols extracted with ether, the solution dried, and the phenols carefully fractionated.

<sup>1</sup> Friedlander's *Fortschritte*, 7, 89 (1903).

**2,2' - Chlorodiphenoxydiphenylmethane**,  $(C_6H_5)_2C(OC_6H_4Cl)_2$ . — The phenoxy compound could be isolated when the reaction between the benzophenone chloride and *o*-chlorophenol was carried out without the use of a solvent, but was more easily prepared, with theoretical yields, if the reaction took place in benzene solution warmed sufficiently to expel the hydrochloric acid gas given off in the reaction as soon as formed. On evaporation of the benzene and the addition of small amounts of alcohol, the chlorophenoxy compound separates out. On recrystallization from hot alcohol, it is obtained quite pure and it then melts at  $191-192^\circ$ .

Calc. for  $C_{26}H_{18}O_2Cl_2$ : Cl, 16.86. Found: Cl, 16.94.

— 12 g. of benzophenone chloride were dissolved in a small amount of carbon disulfide and the temperature of the solution kept down by means of ice-water. To this solution gradually and alternately small amounts of *o*-chlorophenol and aluminum chloride, finely powdered, were added until slightly more than one molecule of each had been used. The product is isolated in the same manner as the bromophenol compound, and it also is crystallized from carbon tetrachloride, from which it separates as a slightly colored material without a sharp melting point. On recrystallization from 60% acetic acid, the quinonoid desmotrope, deep orange and melting at  $118^\circ$ , is obtained. If the product obtained from the carbon tetrachloride solution is dissolved in alcohol, on standing there separates out the benzenoid desmotrope in large, transparent, colorless crystals, melting at  $70-72^\circ$ , with apparent loss of solvent of crystallization.

Calc. for  $C_{19}H_{15}O_2Cl + \frac{1}{2}C_2H_6O$ :  $\frac{1}{2}C_2H_6O$ , 6.9. Found:  $\frac{1}{2}C_2H_6O$ , 6.88.

If the alcohol of crystallization is driven off at a low temperature or by long exposure of the crystalline carbinol over calcium chloride, the product remaining is a white powder melting at  $126^\circ$ , and on recrystallization from benzene, or ether and petroleum ether, the melting point is not changed. Similar to the case with the analogous monobromocarbinol, the method employed for the preparation of the 3-chloro-*p*-hydroxytriphenylcarbinol did not exclude the possibilities of production of the isomeric 3-hydroxy-*p*-chlorocarbinol. That the carbinol prepared by the methods just given is nonetheless the *p*-hydroxy compound was definitely shown by further chlorinating the product obtained from this reaction. We obtained in this manner a dichlorocarbinol identical in every respect with the product obtained by direct chlorination of the *p*-hydroxytriphenylcarbinol, the constitution and properties of which are given later in this paper.

The transformation of the 3-chloro-*p*-hydroxytriphenylcarbinol from the white form to the colored modification takes place not quite as readily as with the corresponding bromocarbinol, as can be seen on comparison of the two sets of curves showing the relative values of dehydration.

48 hrs.	....	4.35

Calculated loss for one molecule of water is 5.78%.

Fig. 9.

**Diphenyl-2-chloroquinomethane.**—The product remaining from the dehydration of either form of the chlorocarbinol consists of the chlorofuchson. It does not differ in properties from the bromofuchson, both of them showing remarkable stability over the guaiacylfuchson under the influence of heat. When crystallized from benzene it melts at 162–3°. On recrystallization from hot glacial acetic acid there separated out deep red crystals containing acetic acid, which is easily driven off at 75°. Here again, as in the instance of the *o*-cresylfuchson acetate, we are inclined to attribute to this compound the constitution of a quinocarbonium salt, namely, diphenyl-2-chloroquinomethane acetate.

Calc. for  $C_{11}H_{14}OCl$ : Cl, 11.42. Found: Cl, 11.70.

**3,5-Dichloro-*p*-hydroxytriphenylcarbinol,**

—This carbinol is best prepared from *p*-hy-

droxytriphenylcarbinol directly. The latter is suspended in carbon tetrachloride and to the cooled mixture a solution of chlorine in the same solvent is slowly added. The carbinol, on chlorination, goes into solution. The solvent is now evaporated and the residue is boiled up with glacial acetic acid. On cooling, dichlorofuchson, m. p. 217°, very little soluble in cold acetic acid, crystallizes out. The hydrolysis of the fuchson to the carbinol, further purification, and the isolation of the two desmotropes is carried out in the same manner as has been described under the 3,5-dibromocarbinol. The dichlorofuchson is darker red than the corresponding dibromo com-

pound, and the quinonoid carbinol possesses also a brighter red color than the dibromocarbinol. Here again, as has been found to be the case with the analogous dibromocarbinol, the benzenoid dichloro compound crystallizes from benzene and from carbon tetrachloride with solvent of crystallization. Furthermore, the two desmotropes cannot be differentiated from each other by their melting points, for both melt at approximately the same temperature,  $134^{\circ}$ . They can be differentiated, however, not merely by the difference in color but also by their respective rates of dehydration on heating.

### VII. Nitro-*p*-Hydroxytriphenylcarbinol.

The reaction between benzophenone chloride and *o*-nitrophenol was in no way similar to any other condensations previously studied. When mixed in the cold without the use of a solvent there was only slight action as judged from the amount of hydrochloric acid given off. Upon the addition of catalytic agents, a drop of sulfuric and addition of hydrochloric acid gas, this action was only slightly increased. At temperatures ranging from  $75$ – $100^{\circ}$  the evolution of gas was increased, but the resulting product was a charred mass from which nothing could be isolated. Recourse was had to methods similar to those employed with the *o*-bromo- and *o*-chlorophenols, but without satisfactory results, whether carbon disulfide or heptane (b. p.  $90^{\circ}$ ), was used. The condensation was finally brought about in the presence of aluminum chloride without the use of solvents, and resulted in the formation of the nitrohydroxycarbinol. 12 g. (1 mol) of benzophenone chloride and 7.5 g. (1.1 mol) of *o*-nitrophenol are mixed in a round-bottom flask and kept cool by surrounding with ice-water. To this mixture were gradually added 7 g. (1 mol) of anhydrous aluminum chloride. After the reaction is at an end, the mixture is heated on the water bath at  $60^{\circ}$ . Too high a temperature should be avoided; otherwise the result is a charred mass. After cooling, the aluminum salt is decomposed in the usual manner, the excess of nitrophenol removed by steam distillation, the product digested with normal alkali, precaution being taken to remove the benzophenone, and the sodium salt of the carbinol finally precipitated by addition of sodium chloride. The sodium salts already mentioned of the various carbinols were in every case white needle-like crystals. In the case of the nitrophenolcarbinol the sodium salt was bright red. The carbinol which results from the water solution of the sodium salt on the addition of acids is almost colorless. On recrystallization from 60% acetic acid, it does not change in color but always precipitates out with only a slight amount of color. It melts at  $97$ – $98^{\circ}$ . Recrystallization from any solvent does not change the melting point.

Calc. for  $C_{19}H_{15}O_4N$ : C, 71; H, 4.71; N, 4.36. Found: C, 70.68; H, 4.353; N, 4.273.

It is barely possible that here we have another instance of substituted triphenylparahydroxycarbinols occurring in but one modification, as is the case in certain carbinols studied in this laboratory by L. C. Johnson and which will be described later. The intense color of the sodium salt, in contradistinction from the carbinol itself, suggests the relation of acinitro to the true nitro compounds, so thoroughly studied by Hantzsch. The substance is now under further investigation.

### Summary.

1. It has been shown in this paper that benzophenone chloride condenses with various ortho-substituted phenols, in some instances requiring no catalytic agent, in others the use of aluminum chloride makes the yields more satisfactory. Under proper conditions this offers an excellent method for the preparation of various *p*-hydroxytriphenylcarbinols.

2. It has been shown that substitution of the groups, CH<sub>3</sub>, OCH<sub>3</sub>, Br, Cl in the ortho positions to the hydroxyl group does not deprive the carbinol of the tendency to tautomerize, and with each carbinol two desmotropic forms have been isolated. The various pairs of tautomers show remarkable similarity, as for example, in their melting points, in every instance the colored compound melting lower than the corresponding white desmotrope. Furthermore, the white higher melting compound, through heat or light energy, is invariably changed to the lower melting isomer.

3. Although as mentioned, the substitution did not hinder the tautomeric tendency in the carbinols studied, it resulted nevertheless in a gradation of this tendency. The various curves of dehydration, if placed on one diagram, would show clearly that at the temperature chosen, 75°, the various white desmotropes differ in their readiness to transform into the corresponding colored modifications, as judged by their rate of loss of water. For example, the monobromo-*p*-hydroxytriphenylcarbinol suffers transformation and subsequent dehydration in one-third the time as the chlorocresylcarbinol. Similarly, the colored modifications differ among themselves, as may be noted from the readiness of dehydration of the guaiacyl colored desmotrope as compared with the chloroguaiacyl colored compound under similar conditions. This, to be sure, does not indicate tautomeric tendency, but rather serves as a measure of the stability with which the two hydroxyl groups linked to one and the same *p*-quinone-carbon atom are held in the various quinoid carbinols, respectively.

4. The colored desmotropic modifications of the carbinols have been shown to possess the quinonoid constitution. The existence of so large a group of desmotropes removes the phenomenon of tautomerism in this series of compounds from the realm of chance, and offers a very strong support of experimental nature to the whole quinocarbonium theory

and to the quinonoid interpretation of the cause of color in the triphenylmethane series in general. This applies in no lesser degree to the free triarylmethyl radicals themselves. In the solid state they are nearly all colorless or only pale yellow, but when they are dissolved in some solvent, like benzene, intensely colored solutions result. We must assume from the evidence presented in this paper that the radicals dissolve with a simultaneous partial transformation to the quinonoid state.

**RESEARCHES ON QUINAZOLINES. XXXIII. A NEW AND SENSITIVE INDICATOR FOR ACIDIMETRY AND ALKALIMETRY, AND FOR THE DETERMINATION OF HYDROGEN-ION CONCENTRATIONS BETWEEN THE LIMITS OF 6 AND 8 ON THE SORENSSEN SCALE.<sup>1</sup>**

BY MARSTON TAYLOR BOGERT AND GEORGE SCATCHARD.<sup>2</sup>

Received June 19, 1916.

**Introductory.**

As a means of measuring hydrogen-ion concentration, the use of an indicator possesses the obvious advantage of convenience of operation, practically instantaneous readings and inexpensive apparatus.

Ostwald's explanation<sup>3</sup> of indicator action as due to an equilibrium between an ion of one color and an un-ionized molecule of another color (or colorless), has been quite generally abandoned in favor of the theory that an equilibrium exists between the two forms in both states.<sup>4</sup>

<sup>1</sup> Sørensen's system of expressing hydrogen-ion concentration has been used throughout, the "Index" ( $P_H$ ) being the negative common logarithm of the concentration of hydrogen ion, i. e., the negative exponent of the power to which 10 must be raised to express this concentration (Sørensen, *Compt. rend. Laboratoire de Carlsberg*, 8 (1909); Fales and Nelson, *THIS JOURNAL*, 37, 2771 (1915)). Thus, the index 6 represents a hydrogen-ion concentration of  $10^{-6}$ , and 8 of  $10^{-8}$ . This provides a single unit for expressing acidity and alkalinity, and one which can be measured directly by the use of the hydrogen electrode. Further, it is the relative and not the absolute change in hydrogen-ion concentration which affects both the electromotive force of the hydrogen electrode and the color of the indicator.

<sup>2</sup> The experimental work upon which this paper is based was carried out by Mr. George Scatchard in partial fulfilment of the requirements for the degree of Doctor of Philosophy under the Faculty of Pure Science of Columbia University.

Acknowledgments are also due to Dr. H. A. Fales, of this University, for much valuable assistance and advice.

<sup>3</sup> *Wissenschaftliche Grundlagen der analytischen Chemie*, 1901, 117.

<sup>4</sup> Stieglitz, *THIS JOURNAL*, 25, 1112 (1903); A. A. Noyes, *Ibid.*, 32, 816 (1910).

Yet, for a satisfactory indicator, just those conditions are necessary which approximate Ostwald's simple hypothesis so closely as to permit the application of the dilution law to them as to a simple dissociation. That is, for a two-color indicator, one tautomer must predominate in the ion and the other in the un-ionized molecule: while, for a one-color indicator, the colored form must be absent in one state. In either case, the equilibria between tautomers must be unaffected by external factors. With these conditions fulfilled, we may then ignore all but the predominating forms.

For a monobasic acid indicator ( $\text{In.H}$ ), the following relation will therefore hold:

$$(\text{H}^+) = K(\text{In.H})/\text{In}^-;$$

and for a monacid basic indicator ( $\text{In.OH}$ ),

$$(\text{H}^+) = K_w/(\text{OH}^-) = K_w(\text{In}^+)/K_B(\text{In.OH})$$

An indicator base may therefore be regarded as an acid with  $K_A = K_w/K_B$ .

We have omitted the term  $\gamma$  for the degree of ionization of the salt which Noyes uses in his equations, because its use assumes that the equilibrium between the tautomers in the un-ionized salt is the same as in the ion, and that the other ion which goes to make up the salt exists in the solution in the same concentration as the indicator ion. The second condition is seldom even approximately realized in practice, the first we do not know about. Since the error introduced by assuming  $\gamma = 1$  is small compared to that made by the other approximations, it does not seem worth while to use the very much more complicated form demanded by an exact expression.

For polybasic acids, or polyacid bases, the relations are more complex, but probably even then a single color change is affected by only one ionization, and the above relation holds at least approximately, which is all that is required for qualitative purposes.

By the depth of color of a one-color indicator, or the tint of a two-color one, the ratio of ionized to un-ionized indicator is measured, and thus the hydrogen-ion concentration. Although theoretically this ratio should vary with the change of hydrogen-ion concentration throughout the whole possible range, there is for every indicator a definite limited region within which this change of concentration is determinable by the color change. Outside this region either the small amount of one color is masked by the large amount of the other, in the case of two-color indicators; or, for one-color indicators, the amount of color is too minute to be visible, or too deep for the recognition of a slight change. The range of usefulness hence varies with the different indicators, but is usually one or two units of index. The location of this particular region of serviceability, depend-

ing as it does upon the ionization constants, naturally differs for different indicators. The location and extent of the serviceable range, and the accuracy of measurement, depend upon the amount of indicator required to give visible color. In general, one-color indicators have wider ranges than two-color ones, because of the masking of one color by preponderating amounts of the other, as already pointed out; and they give more accurate readings because it is easier to estimate depth of color than change of tint.

In titrations where the purpose in using an indicator is merely to determine when a certain definite concentration of hydrogen ion has been reached, the great advantage of a one-color indicator arises from the fact that the easiest of all color changes to detect is the first appearance of color in a colorless solution.

The accuracy of an indicator is impaired by any factors which cause a variation in the equilibrium between the tautomers. Certain substances affect the color change by disturbing the equilibrium without changing the concentration of hydrogen ion. Neutral salts affect most indicators and are particularly troublesome with those of the rosaniline series. Certain organic solvents, like alcohol, likewise often exert a disturbing influence.

Since the use of indicators for determining hydrogen-ion concentration is frequently resorted to in the case of biological liquids, the interfering factors in such solutions are of especial interest, notably the proteins and the commonly used preservatives. The effect of proteins is quite likely due to their colloidal nature, and becomes more serious as the molecular weight and complexity of the indicator increase, being most noticeable with azo indicators of Congo Red type. On the other hand, the disturbing action of the ordinary preservatives, such as chloroform and toluene, is usually due to extraction of the indicator, and those most seriously affected are the basic azo indicators.

Another factor to be reckoned with, is the color of the solution to be titrated. This difficulty may be partially remedied by giving the standard the same color, but it cannot be wholly overcome. For example, a yellow solution would impair but little the usefulness of phenolphthalein, but it would make trouble with methyl orange, and might preclude entirely the use of *p*-nitrophenol; the disturbance caused by a pink solution, on the other hand, would increase in just the opposite direction.

Still another matter of importance, is the permanence of an indicator color, particularly on standing exposed to ordinary daylight. Some indicators, like hematoxylin, run through a rapid series of color changes which make them unsuitable for measuring hydrogen-ion concentration; others fade on account of the precipitation of the indicator; practically all lose their color on long standing in strong daylight. This fading

may be so slow that the standards can be used for several days after they have been made up, or it may be so rapid that the indicator must be added at practically the same instant to the solutions which are to be compared.

For many titrations, an indicator must be used changing near a fixed point, because of the effect of the hydrolysis of the salt formed upon the hydrogen-ion concentration, and the common ion effect of the salt upon the acid or base. Except near this point, the change in hydrogen-ion concentration for a given amount of acid or base added is very slow; as is well illustrated by Hildebrandt's measurements, with a hydrogen electrode, of the hydrogen-ion concentrations at different points in certain titrations.<sup>1</sup> But, for the titration of a strong acid with a strong base; these influences are so slight that, with a proper correction for a blank on the water, the indicator may be selected throughout a wide range. In such cases, the delicacy is greatly increased when the end point is near the neutral point, because the color change depends upon the relative change in concentration, while the volume added affects the absolute change.

Assuming complete ionization, it requires 0.009 cc. of 0.01 molar monobasic acid to change the concentration of 100 cc. from an index of 7 to one of 6, while it requires ten times this amount to change it from 6 to 5, and 100 times to change it from 5 to 4. As the range of dinitrobenzoylene urea is from 6 to 8, it is appropriate to consider here other indicators available for this same change.

Azolitmin changes from red to blue with a change of hydrogen-ion concentration from 4.5 to 8.3; but the color change is too gradual for accurate work, and the indicator is useless in presence of protein.

*p*-Nitrophenol changes from colorless to greenish yellow from 5 to 7, and is but little affected by outside disturbing factors. Its chief objection is its color, which renders it unsuitable for use in artificial light or in yellow solutions.

Alizarin changes from yellow to red from 5.5 to 6.8. It is affected by protein and cannot be used in yellow solutions.

Neutral red changes from red to yellow from 6.8 to 8. It is affected by protein, chloroform or toluene.

Rosolic acid (commercial Coralline) changes from yellow to red from 6.8 to 8. The color change is poor and the indicator is affected by protein.

Cyanine changes from colorless to blue at 7 to 8, but is useless in presence of protein.

Hematoxylin and hematein give too rapid color changes.

Phenolsulfonephthalein changes from yellow to reddish violet from

<sup>1</sup> THIS JOURNAL, 35, 847 (1913).

6.50 to 8.50. The effect of salts and protein upon it is now being studied by Lubs and Clark.<sup>1</sup>

*o*-Cresolsulfonephthalein shows the same range and color change as the last, but its color change is less satisfactory. Lubs and Clark are studying the action of protein and salts upon it.

Bromothymolsulfonephthalein is also being studied by Lubs and Clark in the same way as to the effect of protein and salts. It shows a color change from 6 to 7.25 from yellow to blue.

So far as we are informed, there is no satisfactory indicator now known covering this range of 6 to 8. Sørensen says of this whole region, "il serait certes désirable de trouver des indicateurs supplémentaires."

The color change in the case of dinitrobenzoylene urea is from colorless to greenish yellow, the color developing regularly with the change in hydrogen-ion concentration from 6 to 8. This color change closely resembles that of *p*-nitrophenol, possesses the same advantage as a one-color indicator, and the same disadvantage due to its color being yellow. This is of interest, as the compound is structurally more closely allied to *p*-nitrophenol than to any of the other indicators cited, since it may also be regarded as of nitrophenol type. It is but slightly affected by neutral salts and not at all by chloroform or toluene.

Sørensen found that egg albumen was the most troublesome of all proteins with indicators, but that it did not affect *p*-nitrophenol. Comparative tests with egg albumen showed that dinitrobenzoylene urea is no more disturbed by it than is *p*-nitrophenol. The color of this new indicator fades but slowly. In phosphate solutions<sup>2</sup> it did not fade appreciably in two days, and but very slightly in a week.

Thus, it would appear preferable to rosolic acid (Coralline) for the preparation of neutral ammonium citrate solutions for fertilizer or soil analyses, since the hydrogen ion concentration of such solutions lies near the middle of its range, and it is possible to make much more accurate readings with it than with the older indicator.

In titrations, the acid side of the end point gave an index of 5.93 and the alkaline side 6.09, as measured by electromotive-force determinations with the apparatus described by Fales and Nelson.<sup>3</sup> These tests were made on phosphate solutions, as the reduction of the indicator by the hydrogen made it impossible to carry out these e. m. f. measurements in its presence, and because a buffer was necessary to keep the hydrogen-ion concentration constant. The figures recorded correspond to a change in hydrogen-ion concentration of  $3.6 \times 10^{-7}$ , or less than 0.004 cc. of

<sup>1</sup> *J. Wash. Acad. Sci.*, 5, 609 (1915).

<sup>2</sup> The primary and secondary alkaline phosphate solutions used throughout were prepared as described by Sørensen, *i. e.*, were  $1/15$  molar.

<sup>3</sup> THIS JOURNAL, 37, 2781 (1915).

0.01 molar monoacid alkali to 100 cc. of solution (assuming ionization to be complete). In practice, the change was obtained with one drop of 0.01 molar NaOH. To give an equally distinct change under similar conditions requires in the case of *p*-nitrophenol 5-6 drops, and for methyl orange 10-12. Titrations of 0.01 molar HCl checked to within 0.1%.

This indicator can be used in hot or cold solutions, and its color is unaffected by nitrous acid. It gives a sharp end point with ammonium hydroxide solutions and hydrochloric acid. It can be used with NaOH and acetic acid, but it is impossible to titrate to the first yellow color. It cannot be employed to titrate carbonates, but the error due to small amounts of CO<sub>2</sub> is negligible.

It gives a second color change at 11 to 13, when the yellow color becomes much deeper, but this is too alkaline for most practical purposes. An attempt was made to use this color change for titrations of boric acid with NaOH, but it proved abortive, partly because the indicator gave a pale yellow color on the acid side of the end point, but principally because in such a strongly alkaline solution, a small change in index requires a large amount of alkali.

Dinitrobenzoyleneurea is readily prepared from anthranilic acid, by converting the latter first into the uramino (ureido) acid, which then easily condenses to benzoylene urea,

The benzoylene urea is nitrated with sulfuric and nitric acids, yielding a dinitro derivative, whose monosodium salt is used as the indicator. The location of the two nitro groups has not been definitely determined as yet, although one is quite certainly in position 6. The indicator action may be due solely to keto-enolic tautomerism, or the nitro groups also may play a part by pseudo-acid tautomerism themselves. In this connection, the second color change already noted at 11 to 13 is quite possibly due to the ionization of the second hydrogen.

The study of benzoylene urea and related compounds is being continued, and it is hoped that other serviceable indicators will come to light in the prosecution of the work.

### Experimental.

**Dinitrobenzoylene Urea**, C<sub>8</sub>H<sub>4</sub>O<sub>6</sub>N<sub>4</sub>.—20 g. anthranilic acid were dissolved in 700 cc. water and 15 cc. concentrated hydrochloric acid (calculated, 12 cc.) by warming. The solution was filtered, cooled, a solution of 15 g. KNCO (calculated, 12 g.) in 50 cc. water added slowly with mechanical stirring, this stirring being continued for 20 minutes after

all the  $\text{KNCO}$  solution had been added. The uraminobenzoic acid precipitated as a pasty white mass of microscopic needles. 300 g.  $\text{NaOH}$  were added with cooling. This dissolved the uramino acid and the sodium salt of benzoylene urea soon separated in crystalline form. After standing for four hours, the sodium salt was filtered out, dissolved in a liter of boiling water, precipitated with acetic acid, the free benzoylene urea filtered out, washed with water, and dried at  $120^\circ$ . Yield, 21.8 g., or 92%. The product formed colorless needles, m.  $353.4^\circ$  (corr.), which m. could not be raised by further crystallization.

10 g. of this benzoylene urea were heated on the water bath with 100 cc. concentrated sulfuric acid (which did not quite dissolve it all), and 12 cc. (calculated, 8 cc.) concentrated nitric acid (gr., 1.42) added. Heat was evolved, and the mixture turned bright red, but soon changed to bright yellow. After heating for an hour at  $100^\circ$ , the mixture was cooled and poured into a liter of ice and water, the precipitate filtered out, washed with water and recrystallized from a liter of 50% acetic acid. The crystals were removed, washed and dried at  $120^\circ$ . Yield, 14.4 g., or 92%.

Subs., 0.2026; 0.2786;  $\text{H}_2\text{O}$ , 0.0290, 0.0419;  $\text{CO}_2$ , 0.2846, 0.3895.

Calc. for  $\text{C}_8\text{H}_4\text{O}_4\text{N}_4$ : C, 38.08; H, 1.60. Found: C, 38.31, 38.13; H, 1.60, 1.68.

Subs., 0.1858, 0.1655; 36.60 cc. N at  $17^\circ$  and 765.4 mm.; 32.75 cc. N at  $20^\circ$  and 765.3 mm.

Calc. for  $\text{C}_8\text{H}_4\text{O}_4\text{N}_4$ : N, 22.19. Found: N, 22.28, 22.30.

As thus prepared, the compound formed pale greenish yellow prisms, decomposing at  $274.5^\circ$  (corr.), which decomposition point could not be altered by further recrystallization.

100 cc. of its aqueous solution saturated at  $23^\circ$  gave 0.0164 g. residue at  $110^\circ$  and 100 cc. of the water used gave 0.0007 g. residue. This solubility of 0.0157 g. per 100 cc. is equivalent to 0.00062 mols per liter, and corresponds to 14-15 drops of 0.01 molar indicator solution to 10 cc. of liquid to be tested.

The substance is very difficultly soluble in cold alcohol, or in ether, benzene, toluene, ligroin, chloroform, carbon tetrachloride or carbon disulfide; slightly soluble in acetone, ethyl acetate, cold acetic acid or boiling alcohol; moderately soluble in boiling water; readily soluble in boiling glacial acetic acid. It can be recrystallized from water or acetic acid. In solution of sodium hydroxide or carbonate, it dissolves with a yellow color, but is reprecipitated from such solutions by saturation with  $\text{CO}_2$ .

For the preparation of the sodium salt, 25 g. of the dinitrobenzoylene urea were dissolved in 115 cc. molar  $\text{NaOH}$  and 500 cc. boiling water, the solution filtered and cooled. A mass of long, bright yellow needles crystallized out. These were removed, pressed as dry as possible, and then left over concentrated sulfuric acid in an evacuated desiccator.

The rest of the dinitrobenzoylene urea was recovered by acidifying the filtrate. The sodium salt thus dried *in vacuo* was then heated to constant weight at 140–150°:

0.3195 g. subs. lost 0.0194 g.  $\text{H}_2\text{O}$ . Calc. for  $\text{C}_8\text{H}_5\text{O}_6\text{N}_4\text{Na}\cdot\text{H}_2\text{O}$ :  $\text{H}_2\text{O}$ , 6.17. Found:  $\text{H}_2\text{O}$ , 6.07.

Subs. (dried at 140–50°), 0.3001;  $\text{Na}_2\text{SO}_4$ , 0.0777. Calc. for  $\text{C}_8\text{H}_5\text{O}_6\text{N}_4\text{Na}$ : Na, 8.39. Found: Na, 8.38.

The solubility of the salt at 20° and at 2° was determined by taking a measured volume saturated at the desired temperature, heating to boiling, acidifying with hydrochloric acid, cooling, filtering out the precipitated dinitrobenzoylene urea, and drying to constant weight at 120° in a Gooch crucible. This gives the difference in solubility between the sodium salt and the free dinitrobenzoylene urea.

(1) 50 cc. solution saturated at 20° gave 0.4898 g. dinitrobenzoylene urea, indicating a solubility of 0.0389 mols per liter, or 1.1359 g.  $\text{C}_8\text{H}_5\text{O}_6\text{N}_4\text{Na}\cdot\text{H}_2\text{O}$  per 100 cc.

(2) 50 cc. solution saturated at 2° gave 0.1294 g. dinitrobenzoylene urea, indicating a solubility for the sodium salt of 0.0103 mols per liter, or 0.3008 g. per 100 cc.

In both the above calculations, the solubility of free dinitrobenzoylene urea at the temperature used has been assumed as zero. This, of course, is not strictly accurate, as the free dinitrobenzoylene urea is itself slightly soluble; but it is sufficient for all practical purposes, and those who wish closer figures can readily obtain them from the solubility results recorded above for the free dinitrobenzoylene urea.

The indicator solution was prepared by dissolving 0.292 g. of the salt in 100 cc. water, and was therefore 0.01 molar. The dropper used delivered 22–23 drops per cc. Fifteen drops of this indicator solution in 10 cc. 0.01 molar  $\text{HCl}$  gave no precipitate; 20 drops gave considerable. The solubility is thus about four times the amount ordinarily used in practice.

**Determination of Hydrogen-Ion Concentration.**—Phosphate and borate solutions were prepared as described by Sørensen. To 10 cc. of each, four drops of indicator solution were added. That with an index of 6 gave a colorless solution, while that with an index of 8 gave a distinct greenish yellow, the color developing evenly in the intermediate solutions.

Borate solutions with an index of 9 and 10 gave the same color as those with 8; 11 gave a slightly deeper color. 0.1 molar  $\text{NaOH}$  (index 13) gave a much deeper greenish yellow, one drop of the indicator giving as much color as four drops in a solution with index of 8.

**Effect of Toluene and of Chloroform.**—Phosphate solutions were prepared of index 6.4, 7.0 and 7.6. 30 cc. of each solution were made up, and each of these solutions then divided into three lots of 10 cc. each. These separate lots were then grouped into three sets of three lots each,

one of each index. One set was shaken with excess of toluene and filtered. Another set was given a similar treatment with chloroform. The third set was kept as a blank. Four drops of indicator were then added to each solution. No difference could be detected between the solutions of the same concentration in the three sets.

**Effect of Protein.**—25 cc. of egg white were diluted to 100 cc. with water, filtered, and 2 cc. of this solution added to a mixture of 14 cc. primary and 6 cc. secondary phosphate solution. This was then divided into two 10 cc. portions, to one of which *p*-nitrophenol was added and to the other the new indicator. Both showed an index of 6.60.

**Salt Effect.**—160 cc. secondary phosphate solution and 40 cc. primary phosphate solution were mixed and 12 g. NaCl (approximately molar) added. Electromotive-force measurements of this solution showed an index of 6.74, while the new indicator gave 6.90. Such a solution is more concentrated than any generally measured. The effect is apparently due to the large concentration of  $\text{Na}^+$  ion, which is responsible for the presence of un-ionized salt molecules which are colored like the ion.

**Fading Effect.**—Three sets each were made up of phosphate solutions of index 6.6 and of 7.6. Four drops of indicator were added to one set upon a certain day, to the second set on the second day, and to the third set on the third day. On this third day, no difference could be detected between the three sets of the same concentration. After standing for a week, the first set was compared with freshly prepared standards, with the following results: that with index of 7.6 had faded to 7.45–7.50, and that with index of 6.6 to 6.55–6.60.

**Titration.**—Titrations of 0.01 molar NaOH and HCl, using 10 drops indicator, gave 1.0011, 1.0004, 1.0009 and 1.0016, for the ratio of base to acid.

Titrations of 0.1 molar  $\text{NH}_4\text{OH}$  and HCl, using 10 drops indicator, gave 1.1257, 1.1262 and 1.1261, for the ration of acid to base.

Titrations of 0.1 molar acetic acid and NaOH, using five drops of indicator, gave 1.0129 and 1.0138, for the ratio of base to acid; but it was necessary to titrate by comparison with a color standard, instead of to the first appearance of a yellow color.

**Effect of Temperature on the End Point.**—Two 100 cc. samples of 0.005 molar NaCl (the approximate concentration at end point of titrations of 0.01 molar solutions) were heated to boiling and 10 drops of indicator added. One was titrated to one side of the end point, and the other to the other side. On cooling, no change was observed in the color in either case.

**Effect of Nitrous Acid.**—30 cc. molar HCl were diluted to 200 cc. (making it 0.15 molar), 1.5 g.  $\text{NaNO}_2$  (0.1 molar) added, and 40 drops of indicator (10 drops per 50 cc.). After standing for an hour at room

temperature, the solution was heated to 65° for a few minutes, cooled, and then titrated twice with 0.1 molar NaOH. A sharp end point was obtained in both cases, and the results checked closely, *viz.*, 1.0716 and 1.0715.

### Summary.

A dinitrobenzoylene urea has been discovered whose monosodium salt is a very sensitive indicator for hydrogen-ion concentrations between the limits of 6 and 8 on the Sørensen scale, changing from colorless to greenish yellow.

Structurally, and in its behavior as an indicator, it resembles *p*-nitrophenol more closely than any of the other well-known indicators. Like the latter, its chief disadvantage is its yellow color, which renders it unsuitable for work in artificial light.

It is but slightly affected by neutral salts, not at all by chloroform or toluene, proteins (egg albumen) have no more influence upon it than upon *p*-nitrophenol; its color fades very slightly in a week, and is unchanged by nitrous acid. It can be used in cold or in boiling (100°) solutions. It gives a sharp end point with  $\text{NH}_4\text{OH}$  and  $\text{HCl}$ , but cannot be used to titrate carbonates.

For the preparation of neutral ammonium citrate solutions, for fertilizer or soil analysis, it should prove superior to rosolic acid (commercial Coraline).

It can be prepared easily from anthranilic acid by the method described.

## A COMPARATIVE STUDY OF THE DISTRIBUTION OF UREA IN THE BLOOD AND TISSUES OF CERTAIN VERTEBRATES WITH ESPECIAL REFERENCE TO THE HEN.

BY WALTER G. KARR AND HOWARD B. LEWIS.

Received June 5, 1916.

The problems of protein metabolism and protein requirements of the organism are today among the most absorbing and fundamental in the whole realm of physiological chemistry. Closely associated with these problems is the problem of the formation and distribution of urea, since this has long been recognized as the chief end-product of protein metabolism in the higher vertebrates, with the exception of birds and reptiles, in which its place as the chief end-product of nitrogenous metabolism is taken by the more complex uric acid. Although much work has been done on the relation of urea to the intermediary metabolism of protein and amino acids, many problems remain to be solved, the solution of which is now a possibility with the more suitable and accurate

methods of analysis developed in the last few years. The site of the formation of urea has not been determined, whether its synthesis be a function of the liver only, or one of all the tissues, nor is the significance of the variations of the urea content of the blood and tissues clearly defined. In view of this it has seemed of value to make a comparative study of the urea in the blood and tissues of several species of vertebrates, including also those animals whose main end-product of nitrogen metabolism is not urea.

Many of our recent developments in the knowledge of the rôle of urea in intermediary metabolism are due to the perfection of the methods for the determinations of small amounts of urea. Older methods were disadvantageous in that they required rather large amounts of blood, which necessitated experiments on large animals or the death of the animal to obtain sufficient blood for analysis. They were also inaccurate, as our present methods show us, in that either some of the urea was lost in the removal from the solution of interfering substances, or other substances were broken down and their decomposition products determined as urea. Of our present methods, those of Folin<sup>1</sup> and Benedict<sup>2</sup> have generally given satisfactory results in urine and other macro-analyses. But since they are known to break down the allantoin and a small part of the uric acid, creatinine, etc., quantities which are negligible in a macro-analysis, errors in the determination of small amounts are thereby introduced which render the methods of little value in tissue analysis. The most satisfactory method at present seems to be the urease method of Marshall<sup>3</sup> as modified by Van Slyke and Cullen.<sup>4</sup> The urease method is entirely specific for urea, also short and easy of operation, and with Folin's<sup>5</sup> aeration method for ammonia makes a very suitable and accurate determination of urea. Moreover, no removal of protein or other substance is necessary, thus avoiding loss in that respect.

On the distribution of urea in the animal organism many figures are available, but due to the inaccuracy of the older methods of determination, the figures of the last few years only would seem to be trustworthy. Schöndorff<sup>6</sup> reported a large number of figures on the urea content of tissues, but, due to the methods used, these are all apparently too high. He showed, however, that the distribution of urea was general in the body and the quantities approximately equal in different tissues, although his figures are not very consistent on this point. Marshall and Davis<sup>7</sup>

have given an accurate method for urea analysis in tissues by means of the enzyme urease. They have shown that in the dog urea is distributed approximately equally in all the tissues of the organism with the exception of the fatty tissues, kidneys, and urinary tract, that the figures for normal dogs vary from 18 to 31 mg. urea per 100 cc. or g., and that on injection of urea into the blood stream it is absorbed very rapidly, only about 10% being left in the circulation at the end of the injection. They consider that the low content of urea in fatty tissues is due to the small percentage of water in these tissues and the subsequent decreased power of absorbing the urea, and that the high content of the kidneys and urinary tract is due to saturation with urea which is in the process of excretion from the body. Folín and Denis<sup>1</sup> published analyses of the urea content of the blood of different species, showing that it varies with the species. The same observers found the urea content of human blood quite constant at 11-13 mg. urea N per 100 cc. Schwartz and McGill<sup>2</sup> reported figures from fifteen different authors on the urea content of human blood showing a range from 11 to 25 mg. urea N per 100 cc. Cullen and Ellis<sup>3</sup> have shown that the urea concentrations of human blood and cerebrospinal fluid are practically the same under normal conditions. Denis<sup>4</sup> analyzed the blood of the elasmobranch fish (dog fish, sand shark, and skate) and found the urea content to be much higher than that of mammals (800-1000 mg. urea N per 100 cc. blood). The urea content of the blood of the teleosts (goosefish) on the contrary was lower than that of mammals, being about the same as that found by Folín and Denis<sup>5</sup> for chickens (8-9 mg. urea N per 100 cc. of blood). The urea content of the blood of other fish was about the same as that of mammals. Von Schröder<sup>6</sup> found 2.46-2.71% urea in the blood of sharks and somewhat less in the muscles and liver. Baglioni<sup>7</sup> suggests that this is very important, as the presence of urea in these animals is necessary for the life-processes of the heart and probably all the organs and tissues. No results of the comparative analysis of tissues by the new and accurate methods have been reported other than those of Marshall and Davis<sup>5</sup> on the dog.

In the present series of experiments we have analyzed the urea content of the blood and tissues of various species of vertebrates. The animals were placed under ether anesthesia, bled, and the blood collected in a vessel to which a small amount of potassium oxalate was added to prevent clotting. The tissues were removed, immediately placed in

weighed flasks containing ethyl alcohol and again weighed. The urea content was then determined by the method of Marshall and Davis.<sup>1</sup> The results are reported in Table I.

TABLE I.—THE UREA CONTENT OF THE BLOOD TISSUES OF VARIOUS SPECIES.  
Results Expressed in Mg. Urea per 100 g. of Tissue.

Species.	Blood whole serum.		Liver.	Heart.	Lungs.	Thigh.	Abdomen.	Breast.	Kidney.
Guinea pig 14	26	..	25	22	23	17	16	..	104
Guinea pig 7	26	..	26	23	27	19	31	..	50
Guinea pig 21	45	..	..	..	..	..	..	..	152
Guinea pig 16	52	..	..	..	..	..	..	..	...
Guinea pig A	43	42	..	..	..	..	..	..	...
Rabbit	60	60	65	38	40	32	..	..	155
Turtle 1	..	38	17	..	..	38	..	..	52
Turtle 2	28	..	..	..	..	..	..	..	...
Hen A	6	..	15	11	..	6	..	10	10
Hen 2F	9	..	16	8	..	9	..	10	...
Hen 2C	12	..	..	10	..	11	..	11	...
Hen 2D	6	..	..	5	..	11	..	11	...

The results of the analyses given in Table I show the variations of different species in the urea content of their blood and tissues. In agreement with the work of Bang<sup>2</sup> and Folin and Denis<sup>1</sup> there is considerable variation in the urea content between different species while individual variations of normal animals of the same species tend to fall within rather definite limits. The figures for the content of the blood and tissues of the guinea pig may vary from 25 to 50 mg. and the animal remain in an apparently normal condition. The data agree with those of Marshall and Davis<sup>1</sup> who showed that in the dog the urea was approximately equally distributed in all the tissues with the exception of the fatty tissues and the urinary tract. Thus in normal guinea pigs 7 and 14, the variations between tissues, except those of the urinary tract, were 16-31 mg. and 19-31 mg., respectively. On the other hand, the urea content of the kidneys, due presumably to contamination of the kidney tissue with urine was 104 and 50 mg., respectively. In these analyses and in others made in connection with a study of the influence of certain dietary factors on the urea concentration of the blood and tissues<sup>3</sup> we have observed wide variations in the urea content of the kidneys of guinea pigs maintained under similar experimental conditions (from 50 to 277 mg. per 100 g. tissue). We believe that these variations are to be attributed to differences in the concentration of the urine in the process of secretion at the time the animal was killed. The occurrence of considerable amounts of urea in turtle blood as a representative of the lower vertebrates is also

<sup>1</sup> *Loc. cit.*

<sup>2</sup> *Biochem. Z.*, 72, 104 (1915).

<sup>3</sup> Unpublished data from this laboratory.

of interest. In this connection it is worthy of note that urea has been found uniformly distributed in amounts varying from 20 to 30 mg. per 100 g. of tissue in the crayfish (*Cambarus virilis*).<sup>1</sup>

The results of the analysis of the blood of the hen are somewhat lower than those obtained by Folin<sup>2</sup> as he obtained 8 mg. urea N per 100 cc. These higher results may be due to the fact that he used a different method of analysis. In contrast to that of other animals the urea content of the tissues of the hen is low and that of the kidneys uniform with that of other tissues, which is in agreement with the fact that urea is not the end-product of nitrogenous metabolism in the hen. (Compare also Table II.) Analyses of the kidneys of hens for uric acid by the method of Benedict and Hitchcock<sup>3</sup> made in this laboratory have shown that the uric acid content of these organs is much greater than that of the other tissues as was to be anticipated from the composition of the hen's urine.

In order to determine the relation of urea to the intermediary nitrogenous metabolism in the avian organism, *e. g.*, hen, alanine was injected intramuscularly, the hens allowed to remain 2-5 hrs. and, after being placed under ether anesthesia, bled to death and the blood and tissues analyzed for urea. In one experiment urea was also similarly injected to show the distribution of urea following injection in the hen. The results are given in Table II.

TABLE II.—ANALYSES OF TISSUES OF HENS INJECTED WITH UREA AND ALANINE.  
Results Expressed in Mg. Urea per 100 g. Tissue.

No.	Amount injected.	Hrs. after injection.	Blood whole serum.		Liver.	Breast.	Thigh.	Heart.	Lungs.	Kidneys
C	2.5 g. alanine	2 hrs.	4	..	10	10	7	7	4	..
D	2.5 g. alanine	3 hrs.	4	..	13	9	8	..	..	7
E	2.5 g. alanine	5 hrs.	7	..	..	..	..	..	..	..
2E	2.5 g. alanine	3 hrs.	5 <sup>1</sup> / <sub>2</sub>	4	..	..	..	..	..	..
B	2 g. urea	2 hrs.	77	83	31	45	49	..	..	72
194 <sup>4</sup>										

The results show that when urea is injected into the animal it is transferred to all tissues of the body although apparently more slowly than in mammals.<sup>5</sup> When alanine is injected there is no increase in the urea content of the tissues. This would seem to indicate that urea is not an important intermediary product in the transformation of the amino acids to the final excretory product, uric acid, in the metabolic processes of the hen.

In Table I analyses of the blood of rabbit A, and in Table II of hens

<sup>1</sup> Jewell, unpublished results from this laboratory.

<sup>2</sup> *Loc. cit.*

<sup>3</sup> *J. Biol. Chem.*, 20, 629 (1915).

<sup>4</sup> Sample taken from the site of injection.

<sup>5</sup> Marshall and Davis, *Loc. cit.*

B and 2E, show that the distribution of urea is approximately equal between serum and corpuscles of the blood, which confirms the results found by Bang<sup>1</sup> and older investigators.

### Summary.

Values are given for the normal urea content of the blood and tissues of a number of species of vertebrates.

In vertebrates whose end-product of nitrogenous metabolism is urea, the kidneys are much higher in urea content than are the other tissues in which the urea content is about the same as that of the blood.

Hens injected with alanine do not show any increased amount of urea in the blood and tissues, indicating that urea is not one of the stages in the intermediary metabolism of amino acids in the hen. The kidneys of the hen have the same urea content as the other tissues, showing that urea is not present to any considerable extent in the kidney excretion of the hen.

## ON THE ASSUMED DESTRUCTION OF TRYPSIN BY PEPSIN AND ACID.<sup>2</sup>

BY J. H. LONG AND MARY HULL.

Received June 8, 1916.

This question is approached from two general standpoints. In one case it is a purely physiological one without reference to any therapeutic application whatever; in the second case the importance of the question comes from its bearing on the administration of ferments as remedies in disorders of digestion. Both points of view are interesting and important. In this laboratory the question comes up now as part of a problem dealing with the second point of view, and mainly through queries suggested by certain investigations prosecuted by the Council on Pharmacy and Chemistry of the American Medical Association, and particularly this question: What is the fate of the so-called pancreatins, administered by the mouth, in passing through the stomach? As digestive remedies have these preparations any real value? Do they, in any way, inhibit or diminish the activity of the pepsin in the stomach, or, on the other hand, are the components of the pancreas preparations themselves weakened or destroyed by the pepsin?

In part the queries suggested here are comparatively simple and easily

<sup>1</sup> *Biochem. Z.*, 72, 104 (1915).

<sup>2</sup> This investigation has been made with the assistance of a grant from the Committee on Therapeutic Research, Council on Pharmacy and Chemistry, American Medical Association.

answered. In several papers published from this laboratory<sup>1</sup> satisfactory answers have been given to some of the questions, and much of the older literature is quoted in them. But others of the points involved are evidently far from simple, although at first they would seem susceptible of easy solution. Their study involves the consideration of numerous subsidiary questions, some of which have not yet been fully answered. It is easy to arrange experiments *in vitro*, in which one group of ferments may appear to be readily destroyed by another, but it does not necessarily follow from these that under the conditions obtaining in the body a like result should be expected. In many of the published investigations the methods employed have been so narrowly limited as to fail to answer the last practical question, although doubtless giving correct conclusions for the arbitrarily chosen conditions of the experiment. For example, Mellanby and Woolley<sup>2</sup> in a recent publication have come to the conclusion that trypsin and steapsin are mutually antagonistic and that the latter is rapidly destroyed by the former. This may be true under some conditions, but scarcely under those which obtain practically. In our laboratory we have frequently made pancreatic extracts and mixtures in which both ferments exist and persist through a relatively long period. The stability and mutual action of ferments depend on a multiplicity of conditions which are properly balanced in the animal body, but which appear to present enormous difficulties in the duplication *in vitro*. Concordant and consistent results are, therefore, hard to secure.

In former work, and especially in the papers from this laboratory, referred to above, we believe sufficient evidence has been presented to show that the starch-converting ferment of the pancreas, the amylopsin, is so sensitive to the action of traces of acid and acid plus pepsin that its passage through the stomach must appear extremely doubtful under practical conditions. At the very beginning of the gastric digestion and before enough acid has been secreted to combine with the ingested proteins, amylopsin administered will doubtless persist and some of it may pass through into the duodenum. But with increasing hydrogen-ion concentration the conditions for its existence become less and less favorable.

It is not our intention to discuss in this place the behavior of amylopsin or steapsin, as the facts for the first seem to be pretty well established, while for the second many of the data necessary are as yet lacking. We shall confine our attention to the question of tryptic activity under a number of conditions with reference to peptic digestion.

In the papers quoted above<sup>3</sup> the fact is brought out that trypsin may

<sup>1</sup> Long and Johnson, *THIS JOURNAL*, 35, 897, 1188 (1913); Long and Muhleman, *Arch. Intern. Med.*, 13, 314 (1914).

<sup>2</sup> *J. Physiol.*, 48, 287 (1914).

<sup>3</sup> Long and Johnson, and Long and Muhleman, *Loc. cit.* The literature on this point is discussed.

be incubated with considerable quantities of hydrochloric acid without suffering appreciable loss of strength. In some of these cases of incubation through one-half hour the weight of acid was greatly in excess of the weight of the active tryptic ferment employed. These results have been secured so often and in solutions containing from 100 to 160 mg. of actual acid and 50 mg. of pancreas powder, containing trypsin and not trypsinogen, in 50 cc. of solution, that we are at a loss to understand the statements of Mellanby and Woolley<sup>1</sup> that, while trypsin withstands the action of weak acid pretty well, it is so quickly destroyed in acid of 0.2% strength that nothing can be said of the action of pepsin plus the acid on trypsin. In some of our experiments we have employed trypsin of more than the usual activity, but then the weights were so small that their protein content could not bind much of the acid.

These experiments showed, further, that the addition of pepsin to the acid worked a rapid destruction of the trypsin in some cases, while in others no such destruction was observed. The fate of the trypsin seemed to depend on the relation of the amount of protein present, and this practical point was left for further investigation. Meanwhile somewhat similar findings have been reported by Edie,<sup>2</sup> while Serono and Palozzi<sup>3</sup> reach the conclusion that pepsin and acid of 0.2% strength do not destroy the pancreatic enzymes. In Edie's experiments, in which Benger's ferment solutions were mostly employed, the behavior of small amounts of pepsin with large amounts of trypsin and fibrin in acid solution is studied. Under the conditions there can be no tryptic digestion, it is assumed, but a marked diminution in the extent of the peptic digestion was recognized. This cannot be attributed to any destructive action of the trypsin on pepsin, but the hypothesis is advanced that the trypsin exerts its effect by combining with specific groups of the protein complex in such manner as to prevent the pepsin from attacking them in the normal way. The practical bearings of the observations are somewhat remote because of the relative strengths of the solutions from which the results were obtained.

In investigating the action of pepsin on trypsin small volumes of solutions of the latter were allowed to act on much larger amounts of pepsin in presence of fibrin and sodium carbonate. Under these conditions there could be no peptic digestion of the fibrin, but the normal tryptic action appeared to be distinctly retarded. The same explanation is offered as in the other case. The pepsin is here assumed to combine with the protein in such manner as to protect the groups which the trypsin should attack. It will be seen that this is not quite the problem which

<sup>1</sup> *J. Physiol.*, **47**, 339 (1913-14).

<sup>2</sup> *Biochem. J.*, **8**, 84, 193 (1914).

we have on hand, since we wish to determine the action of pepsin on trypsin in acid solution. These investigations represent the physiological rather than the therapeutic side of the problem. Edie's work agrees fully with ours in showing the comparative stability of trypsin in presence of acid alone.

Serono and Palozzi appear to have worked with glycerol extracts of the pancreas, of their own preparation, obtained by aid of high pressure. These glycerol extracts when mixed with acid to make 0.2% strength could be incubated through 24 hrs. at the body temperature without losing their proteolytic activity. Nothing is said about the amount of protein present in the extracts which might serve as a protection to the trypsin by combining with the acid, but the impression is given that pepsin is practically without action on trypsin.

We have gone over these experiments at some length because they are the latest in the literature, and because, further, they leave the question not much nearer a solution than it was when opposite views were expressed by Ewald, Engesser, Mays and others' years ago. Ewald drew the conclusion from his experiments that trypsin is destroyed by digestion with pepsin and hydrochloric acid. But from the conditions under which his tests were made this result would of necessity follow without proving the point at all. For example, he incubated 700 mg. of pepsin and the same weight of trypsin, the Engesser preparation, with 100 cc. of 0.3% hydrochloric acid through three hours at 40°. As will appear below, destruction of trypsin would quite naturally result with these conditions. Engesser maintained that the preparation contained the "zymogen" rather than the finished trypsin, and for this reason should be very resistant. It appears, however, that he used relatively lower amounts of acid by his method of testing than did Ewald. Mays, noting the discrepancy between these results and the lack of agreement with earlier work of Kuehne on the behavior of trypsin, pointed out that the ferment is weakened or destroyed by acids, and that the rapidity of this destruction is hastened by presence of pepsin. He came to the conclusion, generally not admitted, that trypsin digests protein in acid solution when sufficient excess of protein is present, but overlooked the real condition under which trypsin appears to be stable when acid and pepsin are present. These three papers gave a basis for views which are often advanced, even down to the present time.

We have attacked the problem of the conditions of trypsin destruction in two ways. First by a series of experiments *in vitro* where a number of varying conditions with reference to strength of acid, amount and kind of protein present and resultant hydrogen-ion concentration were

<sup>1</sup> Ewald, *Z. klin. Med.*, 1, 615 (1879); Engesser, *Ibid.*, 2, 192 (1880); Mays, *Maly's Jahrb.*, 10, 298 (1880).

considered, and secondly through animal experiments on dogs with duodenal fistulas or Pawlow pouches, by aid of which the products of reactions might be withdrawn and tested. In a considerable number of cases the stomach contents have been withdrawn by a tube and examined as to the extent of the action. In this paper only the first group of experiments will be reported.

### **The Pepsin-Trypsin Reaction in Vitro.**

In these experiments the pepsin employed was an active commercial product which fully satisfied the requirement of the U. S. Pharmacopoeia, in the digestion of egg albumin. In the preliminary work we used the standard product of Fairchild Brothers and Foster and in the later tests the standard pepsin of Armour and Company. As tryptic preparations we have employed a variety of products. In much of our earlier work we used glycerol extracts of the pancreas of our own preparation. Some of these were freshly made and some had been on hand through long periods, to provide for a possible activation, which, however, did not seem to occur. We finally found it most convenient for comparisons to employ two brands of commercial trypsins from the laboratories of the firms whose pepsins we used. In most of the preliminary trials a product of Fairchild Brothers and Foster was used which had been in the laboratory some time and had lost part of its original activity. Later two other samples from the same firm were drawn in for comparison. In the larger number of routine tests the Armour and Company product was used in the digestions, and where convenient these digestions have been frequently carried out in presence of a phosphate mixture giving a hydrogen ion concentration of  $P_H = 7.7$ . But there are some drawbacks in the use of this buffer solution and the usual sodium carbonate medium found more frequent application. In each of the trial experiments of the short table below 3 g. of prepared moist, flake fibrin, yielding about 900 mg. of dry fibrin, was used in the substrate. This was mixed with 100 mg. of trypsin in 50 cc. of water, plus 50 cc. of approximately 0.4% sodium carbonate. The 100 cc. of mixture was protected by toluene in each case and incubated through 8 hrs. at 38°. Then a slight excess of hydrochloric acid was added and the liquids boiled to expel carbon dioxide. They were then made faintly alkaline to litmus and received an addition of 10 cc. of neutral formaldehyde. The final titrations with 0.2 *N* sodium hydroxide followed, with the results below. In each case a blank test was made with trypsin added from a boiled solution. The soluble nitrogen found in the blank test comes in part from the amino nitrogen of the ferments and in part from the effect of the long incubation. The hydrogen concentration at the end of the incubation was found to be essentially the same for all the mixtures, *viz.*,  $P_H = 8.1$ , which is a favorable concentration for activity.

TABLE I.—STRENGTH OF TRYPSINS.

	<hr/>	<hr/>	<hr/>	<hr/>
	8.55 cc.	9.20 cc.	9.10 cc.	7.95 cc.

In the next few tests, preliminary trials, trypsins 1, 2 and 3 were used; later, in the longer trials, trypsin 4.

It was to be expected that pepsin and trypsin preparations would furnish a certain amount of amino nitrogen in the digestions. The extent of this is suggested by the next tests, where the amount of the ferments used was the same as in the subsequent practical trials.

### Series A. Preliminary Tests.

#### *Pepsin and Trypsin without Additional Protein.*

In each of the following experiments 25 mg. of pepsin, 500 mg. of trypsin in 50 cc. of water and varying amounts of 0.1 *N* hydrochloric acid were made to a constant volume of 100 cc. and incubated through three hours at 38° in small flasks. The liquids were neutralized by the addition of the proper amount of sodium carbonate, well shaken to remove carbon dioxide, and then made up to 200 cc. in each case. These volumes were divided into two equal portions and one 100-cc. portion was boiled in each case to kill the ferments. To all the flasks enough sodium carbonate was added to make the hydrogen concentration the same, *viz.*,  $P_H = 8$ , as determined by preliminary trials. This required nearly 4 cc. of normal carbonate. The flasks were returned to the incubator and kept at 38° through 20 hrs., after which they were all made slightly acid to remove carbon dioxide on boiling, and brought back to litmus neutrality with 0.2 *N* alkali. In each case 10 cc. of neutralized formaldehyde were added and the usual titration made with 0.2 *N* NaOH. In the table below the results of the titrations are given, those with the unboiled trypsin being designated by A and those with the boiled trypsin by B.

TABLE II.—PEPSIN-TRYPSIN DIGESTION WITHOUT ADDED PROTEIN.

B. cc. of 0.2 <i>N</i> NaOH.....	4.4	4.2	4.2	4.2	3.8	3.8	4.3
	<hr/>	<hr/>	<hr/>	<hr/>	<hr/>	<hr/>	<hr/>
	0.0	0.8	0.9	1.0	2.6	2.8	2.5

It is evident that in the first few titrations the effect of the trypsin is practically negligible. The amino acid nitrogen from the peptic digestion and other causes is small and nearly constant, as shown by the blank titrations opposite B. However, when the amount of acid used at the start is below 25 cc. we seem to have a slightly larger weight of liberated amino acid nitrogen. This is possibly due to the self digestion of the

trypsin not destroyed in the acid digestion. The titration value in a flask containing 25 mg. of pepsin, 500 mg. of trypsin and 25 cc. of 0.2 *N* HCl and titrated without incubation was only 2.5 cc. of 0.2 *N* NaOH. It is important to note that the blanks from the action of the acid and pepsin alone are around 4 cc. always.

To test the effect of larger and increasing weights of pepsin in the digestion of fibrin with a constant weight of trypsin present the next series of digestions was carried out at 38°. In each case 3 g. of moist fibrin, equivalent to 0.9 g. of the dry substance, was taken with 500 mg. of trypsin in a volume of 100 cc. of 0.1 *N* HCl. Different weights of pepsin were added, as shown below. The mixtures were digested through three hours. Then enough carbonate was added to neutralize and leave an alkalinity of  $P_H = 8$ , after which a further incubation of three hours was carried out. The properly neutralized liquids were titrated with alkali after the formaldehyde addition in the usual way. The results are shown below.

TABLE III.—PEPSIN-TRYPSIN DIGESTION, WITH PROTEIN.

No.	Pepsin added.	Conditions varied.	Cc. of 0.2 <i>N</i> NaOH reqd
A.....	None	.....	5.5
B.....	50 mg.	.....	14.0
C.....	100 mg.	.....	15.0
D.....	100 mg.	3 hrs, acid digestion only	16.2
E.....	150 mg.	.....	14.5
F.....	150 mg.	both ferments killed	4.0

In A we have the effect of the preëxisting amino acid groups and possibly a slight digestion through the residual trypsin which may have survived the acid digestion in presence of the fibrin. In B and C we have a characteristic pepsin digestion. The flake fibrin disappeared completely so that the opalescent liquid could be easily titrated. In D there could have been no tryptic digestion as the incubation was stopped at the end of the three-hour acid period. The larger alkali volume used in titration has probably no significance. In E the conditions are the same as in B and C, but in view of the result in D it does not appear probable that we have any tryptic digestion here, and, therefore, not in B and C. F serves as a general control for the amount of amino nitrogen made soluble in the incubation alone, or as coming from the ferments themselves. This value subtracted from A leaves a remainder so small as to suggest that the assumed tryptic activity in the latter case must be practically negligible. It was pointed out above that trypsin survives a short acid digestion at this temperature very well, but it is evident that with or without pepsin present an incubation of three hours' duration in a medium containing 365 mg. of hydrochloric acid and 900 mg. of dry fibrin is sufficient to destroy the trypsin. This amount of dry fibrin can bind about 60 mg.

of the acid at the most, to the extent of rendering it inert as regards the ferment. Under tests B, C, D and E it is shown that the amount of amino nitrogen liberated by 150 mg. of pepsin from the given weight of fibrin is not essentially greater than the amount liberated by 50 mg. With the active pepsin used it is likely that the same result would be secured by even a much smaller weight of pepsin.

In the continuation of the preliminary experiments we employed smaller weights of pepsin and acid with the constant weight of 3 g. of moist fibrin and 500 mg. of trypsin in a total volume of 100 cc. Each mixture was incubated through 3 hrs. at 38°, the acid neutralized and the reaction brought to  $P_H = 8.1$  by sodium carbonate. At this point a further 3 g. of fibrin were added and the incubation continued through 20 hrs. at the same temperature. The contents of each flask was made slightly acid and boiled to drive out carbon dioxide, then brought to litmus neutrality, treated with 10 cc. of neutralized formaldehyde and finished in the usual manner. The results are shown in the table below. In half of the experiments the trypsin was killed by boiling in part of the water used for solution and these experiments are designated by the letters A', B', C' and so on.

TABLE IV.—PEPSIN-TRYPSIN DIGESTION WITH FIBRIN.

No.	Vol. 0.1N HCl. Cc.	Wt. of pepsin. Mg.	Vol. of 0.2N NaOH. Cc.	A—A', B—B', C—C', etc. Cc.

F.....	00	00	39.1	
F'.....	00	00	7.5	31.6

Tests F and F' at the bottom of the table are straight trypsin digestions carried out through the 20-hr. period only, in the weak alkaline medium, with the ferment in F' killed at the outset. In A', B', C', D' and E' we have peptic digestions in presence of diminishing amounts of acid. In all the peptic digestions where not less than 25 cc. of acid had been used the fibrin solution was practically complete in the three hours, and in the second, or alkaline digestion, in cases where not over 20 cc. of the acid had been used in the first digestion, the solution went so far that no neutralization precipitate formed when the excess of carbonate was finally destroyed by acid. In all cases the formaldehyde titration was made on the filtered liquid, with exclusion of the neutralization precipitate.

It is seen that in test F' of the table we have a blank of 7.5 cc. of 0.2 N alkali, and following an incubation in which the pepsin was omitted and the trypsin killed. This is larger than was found in Table III, No. F, where a blank of 4 cc. of the alkali is given. The trypsin weights were the same in the two cases. The conditions are not the same, however, since in Table IV we have a 20-hr. digestion period against 6 hrs. for Table III. Some greater solution may follow the longer digestion, and it is, of course, possible that in Table IV the trypsin had not been completely destroyed by the preliminary boiling. It has been pointed out that the resisting power toward heat is greater than was formerly assumed.

Aside from this slight discrepancy it is evident that a tryptic action is present in some of the mixtures of Table IV. With the larger weights of acid employed the peptic activity is marked, and that is shown in A and A', where the difference between the results of the two titrations is not large. The total protein is not sufficient to bind all the acid, and we have in consequence destruction of most of the trypsin. In the following tests, with diminishing weights of acid, the peptic digestions become gradually less, as shown by B', C', D' and E', while the combined digestions are correspondingly increased. The trypsin appears to be less and less injured until we have in E a very marked action, approximating the straight tryptic digestion shown in F. The acid of E is not sufficient to bring about a marked peptic digestion on the one hand, or to weaken the trypsin on the other.

#### Series B. Fibrin Digestion.

The experiments just discussed show beyond question that trypsin is able to withstand the action of pepsin and hydrochloric acid under some conditions, while under other conditions there is, apparently, a destruction of the trypsin in acid solution. More detailed experiments are necessary to bring out the facts, and these follow. Fibrin was used for some of these later experiments, but casein and meat, both raw and cooked, have also been used. In what follows a weaker trypsin was employed.

The general method of experimentation was essentially the same as described above, with this modification. After incubating the mixture of 25 mg. of pepsin, 500 mg. of trypsin, protein and acid, made up to 100 cc., through a period of three hours, and neutralizing then exactly with sodium carbonate, the liquid was made up to 200 cc. This volume was divided into two equal portions, one of which was boiled to kill any trypsin left. Both portions were brought to a  $P_H$  concentration of approximately 8.1 with carbonate and each received an addition of 3 g. of moist fibrin. All the flasks holding the mixtures of the series were incubated through 20 hrs. at 38°, made then slightly acid with hydrochloric acid, boiled to remove carbon dioxide and throw out any neutralization precipitate and the contents filtered. The filtrates were brought to litmus neutrality,

treated with formaldehyde and titrated with 0.2 *N* NaOH in the usual manner.

In these experiments, as distinguished from those of Table IV, there was only one flask incubated for each acid concentration, and in the division for the tryptic digestion in a 100 cc. volume the trypsin concentration would be just half what it was in the earlier experiments, for the new amount of fibrin added. A wider range of acid concentrations in the preliminary digestion was further chosen. In the tables below the results for the unboiled half of the incubated liquid are shown by A, B, etc., while the boiled portions are designated by A', B', etc.

The preliminary acid digestion mixtures contain, in the stronger concentrations, enough acid to saturate the protein, while in the lower concentrations this is not the case. The actual  $P_H$  values for several mixtures, from which others may be interpolated, are given below. The measurements were made at the end of the three-hour digestion period.

Vol. of 0.1 <i>N</i> HCl in 100 cc.	$P_H$ .	$C_H$ .	Vol. of 0.1 <i>N</i> HCl in 100 cc.	$P_H$ .	$C_H$ .
50 cc.	1.81	0.01550	25 cc.	2.58	0.00263
35 cc.	2.24	0.00575	15 cc.	3.18	0.00066

In mixtures containing 25 cc., or less, of the acid the *free* acid present is equivalent to that which dissociates from such protein compounds on solution in water.<sup>1</sup> Such concentrations of acid do not affect the trypsin in any marked degree, it appears. In fact, there may be even a little tryptic digestion in concentrations not greatly different from this, as will be shown in some of our work to follow, and as indicated by experiments of Michaelis and Davidsohn.<sup>2</sup> As stated, the acid values were found at the end of the three-hour digestion period, which is preferable to measurement at the outset. In making such mixtures some time elapses before an equilibrium is reached, as the combination between acid and protein is slow, unless they are ground together.<sup>3</sup> The initial concentrations might appear somewhat greater for this reason, and for the further reason that in a digestion like this the products formed in three hours would combine with a little more of the original acid.

In the later digestion in the slightly alkaline medium a hydrogen concentration of  $P_H = 8.0$  to 8.2, at the start, was found satisfactory. This was secured, in the present series of experiments, by the addition of something less than 4 cc. of normal carbonate for each 100 cc. of digesting liquid. No marked change in the alkalinity follows in a 20-hour digesting period, as illustrated by the short table below. Four mixtures were made up as in the regular acid digestions and carried through to the final di-

<sup>1</sup> Long, *THIS JOURNAL*, 37, 1333 (1915).

<sup>2</sup> *Biochem. Z.*, 36, 280 (1911).

<sup>3</sup> Long and Hull, *THIS JOURNAL*, 37, 1593 (1915).

gestion in alkaline medium. The hydrogen concentrations were found after the 20-hour period, as well as just before the beginning of incubation.

	Vol. of 0.1N HCl in prelim.	50 cc.	22.5 cc.	20 cc.	15 cc.
P <sub>H</sub> before incubation.....		8.0	8.0	8.15	8.15
P <sub>H</sub> after incubation.....		8.6	8.4	8.3	8.3

While the alkali concentrations formerly recommended for tryptic digestions, equivalent to about 0.5% of sodium carbonate, were too high for most mixtures, we have found that something less than half of this gives a good result. The limits need not be as narrow as claimed for the optimum activity by Michaelis and Davidsohn,<sup>1</sup> viz., P<sub>H</sub> = 7.68. Indeed, their own experiments seem to show that the rate of tryptic digestion is not much less at P<sub>H</sub> = 9. In the practical formaldehyde titration employed to measure the results there is some advantage in using the carbonate rather than phosphate mixtures. With these a longer preliminary treatment is necessary to bring the mixtures into condition for titration.

TABLE V.—PEPSIN-TRYPSIN DIGESTION WITH FIBRIN.

No.	Vol. of 0.1N HCl Cc.	Vol. of 0.2N NaOH. Cc.	A—A', etc.	General appearance.

M	00	26.4		Complete tryptic digestion
M'	00	7.2	19.2	

<sup>1</sup> *Loc. cit.*

With these explanations of general relations which hold for all the mixtures to follow we present this table as showing the results of the digestions under the modified conditions.

L, L', M, and M' are straight tryptic digestions through 20 hrs. only, and with 3 grams of fibrin only. For the mixtures with boiled trypsin we have here rather large blanks, which come from the gradual solution or hydrolysis of fibrin through long contact with the weak alkaline liquid, and in which the protein dissolved is not thrown out by the final neutralization. But they come in part from the greater weight of soluble trypsin used here, as in these digestions the 500 mg. of trypsin was not divided into two portions, finally, as in the other cases. With this explanation it appears that the effect in K is almost as strong as in the L and M tests.

In comparing with Table IV it must be kept in mind that in that series the 100 cc. volumes with 500 mg. of trypsin were not divided at the end of the acid digestion, as here. In comparing the results in the above table among themselves it is evident that we have for the incubations with the higher acid concentrations peptic digestion only, plus the slight hydrolysis effect. As the acid concentration falls the higher titrations following the tryptic digestions become very apparent and the increase can be explained only through the activity of the residual trypsin. The H, I, J, K and L volumes differ from the H', I', J', K' and L' volumes only in this that the ferment was killed in the latter cases and not in the former. In the first set of flasks the trypsin, in part at least, must survive the acid incubation where this acid is diminished in activity by combining to a certain degree with the fibrin.

Attention must be called to the fact that the volumes of alkali used in the titrations of the contents of the flasks in which the trypsin had been killed before the final incubation are very constant throughout. This is interpreted as indicating the effect of the primary peptic digestion. But this view does not fully describe the situation. Even where there is no peptic digestion there is always some hydrolysis by reason of the long incubations, first in acid and then in alkaline medium, and the products remain in solution after the usual neutralization.

#### Series C. Casein Digestion.

In a manner similar to that shown for the fibrin digestions we have carried out a series of digestions with casein as the substrate, using in each case 1 g. of the pure dry substance in the preliminary incubations. The casein employed was made in the laboratory by the usual Hammarsten process and was light and easily soluble in the proper amount of weak alkali. A second gram was added for the tryptic digestions after the division of the original volume into two halves. Enough sodium carbonate was added to each flask to make a soluble salt of this casein and then the usual further amount to bring the reaction to the desired  $P_H$  value of

about 8.1. In the table below the boiled trypsin flasks are indicated by the prime letters, as before.

TABLE VI.—PEPSIN-TRYPSIN DIGESTION WITH CASEIN.

No.	Vol. of 0.1N HCl. Cc.	Vol. of 0.2N NaOH. Cc.	A—A', etc. Cc.	General appearance.
A	50	16.0		In all of the flasks the casein became pretty thoroughly digested in the acid incubation.

The survival of the trypsin is clearly shown in the tests with the liquids containing the lower acid concentrations. The I experiments show the effects of tryptic digestion plus hydrolysis through the alkali in the long incubation. It is evident that this incubation can in time accomplish a part of the effect which is reached in the much shorter peptic digestion, as far as the amino acid titration is concerned. There appears to be some tryptic digestion in the flasks with even the highest acid concentrations, and this may be due to a greater initial combination of the protein with acid, leaving the latter less active in its trypsin destroying power. This will be illustrated in discussing the behavior of meat below. There is a second possibility here which must be referred to, and that is this that the trypsin may combine with the excess of protein in such a manner as to be protected more or less perfectly from the pepsin-acid action. This view will be taken up later.

#### Series D. Meat Digestion.

Three sets of tests have been carried out here, two with raw meat and one with cooked meat, and under the same general conditions as have been described for the fibrin and casein. The meat used in the raw condition was thoroughly washed to remove blood and easily soluble salts and then pressed out to eliminate the excess of water. In each case 4 g. were taken to make up the substrate and mixed with pepsin, trypsin and acid to make up a volume of 100 cc. as before. The digestions, neutraliza-

tions, division of the volume and addition of more meat for the tryptic digestions were carried out as before. These two sets of trials with raw meat were made six months apart and are reported separately to show about what degree of constancy may be expected under the conditions of the tests.

I	25	32.4		
I'	25	19.5	12.9	100 mg. of pepsin used.

At first sight it is apparent from these tables that a marked liberation of amino acid nitrogen occurs in the mixtures with the higher hydrochloric acid concentrations. To some extent this was noticed in the casein digestions; as distinguished from those with fibrin, but the dry casein

weights were a little larger than the dry fibrin weights which might account for a somewhat greater binding of acid. But such an explanation does not hold here where the action is pronounced. The four grams of moist, raw meat used in the initial incubations contained ordinarily less than a gram of actual protein. In grinding different lots of meat and washing as described, the Kjeldahl determinations have given amounts of nitrogen corresponding to a range of 0.9 g. to 1.0 g. of protein. A mean of 0.95 g. may be taken for the pulp employed here, which is a little greater than the fibrin weight. The acid-binding power of this meat is not greater than was found for the fibrin, as the following results of experiments conducted as were those with fibrin show. In each incubation 4 g. of meat with constant amounts of pepsin and trypsin and varying acid were employed.

Vol. of 0.1 N HCl in 100 cc.	P <sub>H</sub> .	C <sub>H</sub> .	Vol. of 0.1 N HCl in 100 cc.	P <sub>H</sub> .	C <sub>H</sub> .
50 cc.	1.74	0.0182	25 cc.	2.51	0.0031
35 cc.	2.06	0.0087	15 cc.	2.94	0.0011

In fact, the residual ion concentration, while small, appears to be greater than with the liquids secured from the fibrin experiments, from which it follows that the apparent tryptic activity in this case cannot be attributed to a lower hydrogen ion value, as was suggested above as a possibility.

It is well known that trypsin has a marked tendency to attach itself to certain protein groups and the meat proteins may have this binding and protecting power in a degree more marked than obtains with fibrin or casein. This brings us back to the hypothesis of Edie,<sup>1</sup> advanced to account for lowered pepsin activity in presence of trypsin, but the binding power of the protein may be just as important in holding and protecting the ferment as it is in holding the acid. In the one case we have a lowered hydrogen-ion concentration, while in the other the specific group of the ferment on which the acid may act destructively may be the one through which the ferment is linked to the protein. With high acidity this linkage would be broken with following destruction of the ferment. On the other hand, in the case of the low hydrogen-ion concentration, the stimulating value alone of these ions might come into play, with consequent solution of the protein linked up with the ferment.

The digestion tests with cooked meat were made in the same manner and with the same proportions. Since meat loses water in cooking the 4 g. taken for each mixture must represent a somewhat larger weight of real protein than is the case with the moist meat. The acid binding power would be correspondingly greater, which seems to show in some of the experiments.

<sup>1</sup> *Loc. cit.*

TABLE VIII.—PEPSIN-TRYPSIN DIGESTION WITH COOKED MEAT.

No.	Vol. of 0.1N HCl. Cc.	Vol. of 0.2N NaOH. Cc.	A—A', etc. Cc.	General appearance.
A	50	17.9		Most of the flakes of meat disappeared during the peptic digestion, but a fine sediment settled. A precipitate formed on neutralization which was larger than with the raw meat.
A'	50	10.0	7.9	
B	45	18.5		
B'	45	9.3	9.2	In the appearance of the flasks after the second digestion there was not much difference between the boiled and unboiled ferment portions.
C	40	17.6		
C'	40	9.3	8.3	
D	35	21.2		The trypsin ferment was killed in both I and I'.
D'	35	9.0	12.2	
E	30	19.8		
E'	30	8.7	11.1	
F	25	23.5		
F'	25	9.7	13.8	
G	20	25.1		
G'	20	10.0	15.1	
H	15	24.7		
H'	15	9.3	15.4	
I	15	9.5		
I'	15	9.5		

We have here the same general situation noticed in the digestions of the raw meat samples. In the trials with the weaker acid in the substrate the persistence of the trypsin is very apparent, while in the other cases the residual digestion is smaller but constant. In two experiments to determine the hydrogen concentration at the end of the peptic digestion of cooked meat under the conditions as obtaining above we found these results for liquids filtered from the flasks made up with 4 g. of cooked meat and 50 cc. and 25 cc. of the 0.1 N acid in 100 cc.

50 cc. flask.....	$P_H = 2.03$	$C_H = 0.00927$
25 cc. flask.....	$P_H = 2.61$	$C_H = 0.00245$

These degrees of acidity are so extremely small that we can well understand how the tryptic activity may persist to some extent. As pointed out in a previously quoted paper<sup>1</sup> peptic digestion begins to slow down at a concentration of hydrogen ions in the neighborhood of  $P_H = 2.60$ . The acid present is pretty well bound to the protein in these cases and not enough is free to seriously interfere with the trypsin.

In the discussions above the effects observed at the end of the initial incubation are spoken of as due to "peptic" digestion. This expression is used largely for convenience and includes the effects of simple incubation in producing hydrolysis under the conditions. The ordinary protein bodies when brought into solution in any manner show some acid groups by the formaldehyde titration, but in some cases the apparent effect may be due to the protein split products in the ferments themselves. It was formerly held that in the ordinary short pepsin digestion not many

<sup>1</sup> Long; THIS JOURNAL, 37, 1333 (1915).

peptide bonds are loosened in such a manner as to show anything in this titration. This view seems to have been held, for example, by Soerensen<sup>1</sup> himself, who introduced the general method. But enough work has been done since to demonstrate the value of the scheme in just such studies as the above. In a paper by J. Christiansen<sup>2</sup> some interesting information is given as to the extent of the preformed acid groups in some of the commercial ferments and the extent of the liberation of new groups by self digestion. The time element comes in here as an important factor.

But we are not concerned with the extent of the real peptic splitting in the initial incubation, or how much of the carboxyl measured here, by the titration after addition of formaldehyde, is due to a splitting just completed, as distinguished from the carboxyl of the ferments, etc. It is the *increase* of the carboxyl in the second incubation which interests, and under the conditions as brought out there seems to be no question as to the part taken by the trypsin here. All the results secured point in the same direction and to the conclusion that the pancreatic ferment persists through the acid incubation, provided this acid is sufficiently bound by protein to bring the hydrogen-ion concentration down to certain values.

This fact must have an important bearing on the answer to the practical question proposed at the beginning of the paper, which amounts to this: Will trypsin administered by the mouth persist in the stomach and retain sufficient activity to aid in proteolytic digestion in the duodenum? It is evidently true that trypsin when given in relatively large amount and in presence of protein possesses the degree of resisting power requisite for this. Not only does trypsin appear to resist the action of pepsin and acid under the conditions described above but it seems further likely that it is able to bring about some degree of digestion in acid solution which is more marked with some proteins than with others. This kind of activity toward fibrin seems to be less marked than with casein or meat, which may depend on some peculiar binding power or configuration in the fibrin complex as distinguished from the others.

It has been pointed out above that the work of Michaelis and Davidsohn<sup>3</sup> seems to indicate some slight degree of tryptic activity in low acid concentrations, while the same conclusion evidently follows from the studies of Mays<sup>3</sup> already quoted. That tryptic digestion, while greatly impeded in hydrochloric acid solutions, may go on very well in presence of lactic acid or weak acetic acid was shown in the investigations of Lindberger<sup>4</sup> who attempted to account for the protein digestion in the acid duodenal

<sup>1</sup> *Biochem. Z.*, 7, 45 (1907); 21, 289 (1909).

<sup>2</sup> *Ibid.*, 46, 50 (1912).

<sup>3</sup> *Loc. cit.*

<sup>4</sup> *Maly's Jahresh.*, 13, 280 (1883). From the Swedish. Reviewed at length by Hammarsten.

tract of the dog. At that period the relation of acidity to hydrogen-ion concentration was not known. Weak lactic acid furnished the proper medium for the purpose. The commonly accepted view that trypsin is readily destroyed by acids and that it can exert its peculiar behavior only in alkaline solutions follows, in part, from the assumed alkaline character of the pancreatic juice which is able to neutralize completely the acid chyme and leave a marked degree of alkalinity. Many recent observations have shown that the alkalinity of the pancreatic juice is often less than formerly considered "normal." The mixed duodenal fluid in dogs is frequently found to be not alkaline at all. It is also possible, as has indeed been frequently suggested, that for the initial solution and superficial splitting of the protein through trypsin a greater degree of alkalinity is called for than is favorable in the subsequent deep-seated loosening of peptide bonds. If the initial hydrolysis is accomplished through the action of pepsin and acid a nearly neutral medium might furnish the optimum condition for the later cleavage.

In recent papers by Long and Fenger<sup>1</sup> it has been shown that the press juice of the pancreas of hogs, sheep and cattle is distinctly acid and constantly so. More recent observations of Dr. Fenger of the Research Laboratories of Armour and Company and Mr. Nelson of this laboratory, as yet unpublished, have shown that in the juice of the duct of hogs, noted immediately after killing, the reaction is as often acid as alkaline. This undoubtedly bears some relation to the time of last feeding, but the result cannot be ascribed to the presence of traces of acid chyme which might have penetrated the duct from the duodenum. When expressed in terms of hydrogen-ion concentration the mixed duodenal fluid may, perhaps, be more often alkaline than acid, but the degree of alkalinity is so slight and so much lower than usually assumed that there appears to be no physiological necessity for the assumption that trypsin can act *only* in an alkaline medium, or that it is readily destroyed by weak acids of a concentration of physiological importance.

Coming now to a practical side of the discussion this observation is in order. While it is undoubtedly true that trypsin is able to withstand incubation with pepsin and acid in presence of protein sufficient to give a certain low resultant concentration of hydrogen ions, and while it is true that a certain degree of tryptic digestion may be possible in a medium in which the hydrogen-ion concentration is apparently greater than  $10^{-7}$  it does not follow that the practical value of tablets or powders containing a few milligrams of trypsin along with pepsin is worth considering. In the above experiments we have dealt with relatively large weights, and even greater amounts might have to be administered to have much effect in the conditions of the stomach. The most important factor in this

<sup>1</sup> THIS JOURNAL, 37, 2213 (1915); 38, 1115 (1916).

connection is not the absolute weight of hydrochloric acid or pepsin present but the relation of one to the other, and the resultant hydrogen-ion concentration.

### Summary.

It has been shown in previous papers from this laboratory, as well as by other investigators, that trypsin may be incubated with HCl of  $P_H = 1.5$  through half an hour or longer without appreciable loss of strength. In presence of pepsin the tryptic power is rapidly lost.

However, if sufficient protein is likewise present the acid, in combining with it, is unable to destroy in the same degree. When the acid concentration is reduced in this manner to  $P_H = 2.6$ , or below, tryptic activity persists, even through several hours at the temperature of the body. This is a practical condition which very commonly obtains in the human stomach. An active tryptic ferment would unquestionably pass with the chyme, in part at least, into the duodenum where the  $P_H$  value is quickly reduced to 6.5, or lower, and there be able to produce a normal proteolytic digestion of some degree.

From the above experiments it appears further likely that some actual protein splitting is accomplished by trypsin at a  $P_H$  concentration of 1.8 with certain types of proteins. The rapidity of this proteolysis must be slight, however, and the practical importance low.

Our thanks are due to Mr. H. V. Atkinson for assistance in part of this investigation.

## EXPERIMENTS UPON THE AMYLASE OF *ASPERGILLUS* *ORYZAE*.

BY H. C. SHERMAN AND A. P. TANBERG.

Received June 19, 1916.

The amylase produced by the fungus *Aspergillus oryzae* has been known to science since about 1875 after having been used empirically in Japan for centuries. It forms the chief active constituent of taka-diastrase, introduced by Takamine in 1898,<sup>1</sup> which is prepared by growing the fungus on wheat bran, extracting with water and precipitating by the addition of alcohol in such quantity as to give a concentration of 70% alcohol by volume.

The present study was undertaken with the object of purifying the amylase as far as practicable and comparing its nature and properties

<sup>1</sup> *J. Soc. Chem. Ind.*, 17, 118.

with those of the pancreatic and malt amylases previously studied in this laboratory.<sup>1</sup>

The taka-diastase used as the starting point in our work consisted of three lots kindly furnished us by Parke, Davis & Company, and a smaller lot, of considerably higher diastatic power than the other three, for which we are indebted to Dr. Jokichi Takamine. These four lots are designated in the following pages as Samples I, II, III, and IV, and possessed diastatic powers ("new scale") of 18, 23, 18 and 118, respectively. The material was a fine, white or yellowish white powder. The first three samples were soluble to the extent of about eighty-five per cent., while Sample IV was almost completely soluble, in ten parts of cold water.

The starch used in all determinations of saccharogenic and amylolytic power was Merck's soluble potato starch prepared by the Lintner method.<sup>2</sup> The moisture which the air-dry starch contained was determined and allowed for. In determining activities of enzyme preparations allowance was also made for the slight reducing action of the starch upon Fehling solution. The very slight acidity of the starch was corrected by adding to each starch solution as prepared enough hundredth-normal alkali to make it exactly neutral to rosolic acid indicator.

In the use of triple-distilled water, special glassware, etc., and in the technique of determination of diastatic powers (both amylolytic and saccharogenic) the methods and precautions described in connection with previous work in this laboratory<sup>3</sup> were followed.

### Effects of Added Electrolyte.

In order to establish the conditions for determining the activity of this amylase a number of experiments upon the effects of added electrolytes were performed, since the statements on this point to be found in the literature appear contradictory and are in most cases only qualitative. In the present investigation the effects of the various electrolytes tested were studied by careful quantitative determinations of saccharogenic or amylolytic power in the absence of the electrolyte and in the presence of accurately measured additions in the same manner as in the experiments upon malt amylase previously reported.<sup>4</sup> For the sake of economy of space, however, the data of the individual measurements will not be reproduced here but only the general results obtained with each of the added electrolytes will be given.

**Upon the Saccharogenic Action, sodium chloride and potassium chloride** had very little, if any, effect. The activity seemed to be very slightly

<sup>1</sup> THIS JOURNAL, 32, 1073, 1087; 33, 1195; 34, 1104; 35, 1617, 1784, 1790; 37, 623, 643, 1305.

<sup>2</sup> Lintner, *J. prakt. Chem.*, [2] 34, 378.

<sup>3</sup> Sherman and Thomas, THIS JOURNAL, 37, 627, 628, 634.

<sup>4</sup> Sherman and Thomas, *ibid.*, 37, 628-641.

accelerated by these salts at a concentration of 0.0005 molar but the difference was scarcely greater than the probable error of experiment. At concentrations of 0.01 molar and above there appeared a very slight retarding effect. *Primary sodium* (or *potassium*) *phosphate* had no appreciable effect upon the saccharogenic activity of commercial taka-dias-tase, but when tested upon some of the purified amylase preparations described below, primary sodium phosphate in concentrations of 0.002 to 0.014 molar was found to have a slight accelerating action, the optimum being at 0.005 to 0.008 molar. *Hydrochloric* and *sulfuric acids* (tested upon commercial taka-dias-tase) appeared to have a scarcely perceptible accelerating action at very low concentrations, not above 0.0001 normal. At higher concentrations of these acids the action of the enzyme was retarded. *Phosphoric acid* exerted a similar scarcely perceptible activating effect at 0.0003 molar concentration and a retarding influence when added in larger quantity. *Secondary sodium phosphate* had a well marked inhibitory effect.

**Upon the Amyloclastic Action** the effects of added electrolytes were found to be qualitatively similar to the effects on saccharogenic activity, but quantitatively they were much more pronounced. On account of the relatively large experimental error, neither the optimum concentration of the electrolyte nor its quantitative influence upon the activity could be measured with any great exactness. *Sodium and potassium chlorides* at optimum concentrations of 0.02 to 0.08 molar augmented the amyloclastic action to about ten times that observed in the absence of added electrolyte. *Primary sodium and potassium phosphates* at concentrations of 0.02 to 0.026 molar also increased amyloclastic action about ten fold over that found without added electrolyte. *Hydrochloric and sulfuric acids* at concentrations of 0.0001 to 0.0002 normal increased amyloclastic action about eight fold. *Secondary sodium phosphate* had a decided inhibitory effect upon the amyloclastic action of the enzyme.

### Purification Experiments.

After the experiments described above had sufficiently established the conditions influencing the activity of this amylase, experiments were undertaken upon the purification of the enzyme, guided by quantitative measurements of the activity of the products obtained.

The material used in most of the experiments was commercial taka-dias-tase, but for a few of the latest experiments we used material of higher activity furnished by Dr. Takamine.

The method developed in this laboratory for the purification of pancreatic amylase<sup>1</sup> was first applied and yielded a product (Preparation 1) having a diastatic power of 150 ("new scale"). The method which had

<sup>1</sup> Sherman and Schlesinger, *THIS JOURNAL*, 34, 1105 (1912).

been found successful with malt amylase<sup>1</sup> was then tried. This product (Preparation 2) had a power of 90 ("new scale").

After these preliminary experiments, the purification was studied step by step, as follows:

**I. Fractional Precipitation with Alcohol.**—A study of the fractions obtained by the addition of increasing amounts of alcohol showed that the fraction of greatest activity was that which precipitated between 60% and 65% of alcohol (by volume). By a single such fractional precipitation it was possible to obtain a Preparation, 5a, with a diastatic power of 118. Dialysis with subsequent precipitation increased the power of this fraction to 128 (Preparation 8a).

**II. Fractional Precipitation with Alcohol and Sodium Chloride.**—In the course of the work on precipitation with alcohol it was found that often when the addition of alcohol alone was ineffective, a precipitate could be obtained on the addition of a little sodium chloride. In most of the later preparations sodium chloride was, therefore, used for this purpose, and was found, not only to increase the yield, but also to result in a more effective fractionation. Thus, in Preparation 14, the 60–65% alcohol fraction had a power of 179, and dialysis preceding the precipitation with alcohol and sodium chloride increased the power still further to 193.

It was also found in Preparation 12, that the sticky precipitates often obtained could be readily "hardened" by treatment with absolute alcohol and ether. This treatment not only facilitated the drying, but gave a material lighter in color and of slightly higher power. This procedure was followed, therefore, in all subsequent preparations.

In Preparations 17 and 19 the final precipitate was further fractioned into two parts, that precipitated at 60–62.5% and that at 62.5–65% of alcohol; but this additional fractionation did not result in any improvement of the final product.

Acetone was used instead of alcohol in Preparation 18, but no advantage was found in this modification of the method.

**III. Precipitation with Ammonium Sulfate.**—If the active material of taka-diastase is at all similar in chemical nature to the amylases of pancreatin and malt, the method of purification should include precipitation by some precipitant which would separate protein from carbohydrates. In Preparation 21 the procedure consisted in precipitation with ammonium sulfate, dialysis of a solution of the precipitate thus obtained and reprecipitation with alcohol. By this means there was obtained a preparation with a power close to 500, *i. e.*, about thirty times the diastatic power of the original material.

The fact that the highest power was obtained in the 60–65% alcohol

<sup>1</sup> Sherman and Schlesinger, *THIS JOURNAL*, 35, 1621 (1913).

fraction before precipitation with ammonium sulfate, and after such treatment in the 65-70% fraction, seems to indicate either that the other substances originally present exert a considerable influence upon the solubility of the enzyme in mixtures of alcohol and water, or that the nature of the active material is altered when it is precipitated and redissolved.

All of the preparations except those numbered 20, 22 and 23, were made from the three lots of commercial taka-diastase described above. In making these three (20, 22 and 23), Sample IV was used. This material gave by simple precipitation with alcohol and sodium chloride, a 60-65% alcohol fraction with a power of 392, while the procedure described above, involving precipitation with ammonium sulfate, yielded three precipitates with powers over 500.

### Data of Typical Experiments.

**Preparation 15.**—20 grams of Sample II dissolved in 200 cc. water; freed from insoluble residue by centrifuge; alcohol added to 60%, precipitate rejected, alcohol added to 65% and resulting precipitate dissolved in 65 cc. water; dialyzed in collodion sacs against 1000 cc. water for 37 hours at 5° to 7°, the dialyzate being changed at the end of 14 hours. The dialyzed solution was precipitated with 3 volumes of 95% alcohol, centrifuged and the precipitate washed with absolute alcohol and ether and dried in desiccator over sulfuric acid. Yield, 0.45 gram; Power 193 ("new scale").

**Preparation 20.**—10 grams Sample IV dissolved in 100 cc. water and purification continued as in Preparation 15 except that time of dialysis was 23 hours. Yield, 0.275 gram; Power 392 ("new scale").

**Preparation 21.**—10 g. Sample III, precipitated from solution in 100 cc. of water by 60 grams of ammonium sulfate. Precipitate dissolved in 80 cc. water, dialyzed against 800 cc. distilled water for 37 hours, with changes at end of 11 and 18 hours. Precipitated with alcohol and sodium chloride:

- (a) 0-60% (774 mg. sodium chloride)..... Power, 52.
- (b) 60-65% (325 mg. sodium chloride)..... Power, 191.
- (c) 65-70% (132 mg. sodium chloride), yield 0.1 g. Power, 498.

**Preparation 22.**—20 g. Sample IV, 200 cc. water, precipitated by 120 g. ammonium sulfate. Precipitate dissolved and dialyzed for 40 hours. Reprecipitated with alcohol as follows:

- (a) 0-60%..... Power, 209.
- (b) 60-65%, yield 0.5 gram..... Power, 502.
- (c) 65-70%, yield 0.2 gram..... Power, 545.

**Preparation 23.**—10 g. Sample IV, precipitated with ammonium sulfate, redissolved and reprecipitated with ammonium sulfate, dialyzed against distilled water, and precipitated as follows with alcohol and sodium chloride:

- (a) 0-60%..... Power, 108.
- (b) 60-65%..... Power, 236.
- (c) 65-70%, yield 0.1 gram..... Power, 535.

### Composition and Reactions.

The following table gives a brief summary of certain analytical data obtained on the three samples of commercial taka-diastase used, and on four laboratory preparations of increasing activity:

Designation.	Diastatic power. "New scale."	Moisture. %.	Ash (dry basis). %.	Nitrogen (calculated to dry, ash-free material). %.
Sample I.....	18	3.69	12.18	1.63
Sample II.....	23	3.33	14.95	2.69
Sample III.....	18	5.72	18.49	2.38
Preparation 10.....	81	7.10	5.39	3.81
Preparation 15.....	193	5.98	2.42	5.37
Preparation 20b.....	392	4.11	2.50	8.13
Preparation 22b.....	502	5.29	2.13	10.84

It will be noted that there is a very slight decrease in ash content as the power of the preparations increases from about 200 to over 500. The amount of ash in these preparations is comparable with that observed in malt and pancreatic amylase preparations obtained by somewhat similar methods of purification.

The increase in nitrogen content with increase in power shows that the substances which the purification process rejects contain less nitrogen than the enzyme-rich material which is retained, and suggests that the enzyme is composed either wholly or in part of nitrogenous material.

Especial interest attaches, therefore, to the behavior of the purified preparation when subjected to color reactions which are more or less characteristic of proteins as a group. The Hopkins-Cole test for tryptophan, the Millon reaction and the xanthoproteic reaction were applied to a typical purified preparation (No. 22) and all gave pronounced positive results.

This preparation also gave a blue-violet biuret test. When a solution of the material was boiled a coagulum appeared which gave a blue-violet biuret, while the filtrate from this coagulum gave a pink biuret test.

#### Relation between the Saccharogenic and Amyloclastic Powers.

In analogy with the comparison previously given of pancreatic and malt amylases,<sup>1</sup> the following data obtained on typical preparations made from taka-diastase are of interest:

Designation.	Power. "New scale."	Wohlgemuth figure.	"Amyloclastic power."	"Saccharogenic power."	Ratio.
Sample I.....	18	30,000	300	42	7 : 1
Preparation 15.....	194	266,600	2,660	438	6 : 1
Preparation 20b.....	392	715,000	7,150	880	8 : 1
Preparation 21c.....	498	910,000	9,100	1104	8 : 1
Preparation 22c.....	545	1,125,000	11,250	1200	9 : 1

"Amyloclastic power" shows the parts by weight of starch completely hydrolyzed to products giving no blue or violet color with iodine after digestion at 40° for thirty minutes.

"Saccharogenic power" shows the parts of maltose formed, at 40° in thirty minutes, by the enzyme acting on an excess of starch under

<sup>1</sup> Sherman and Schlesinger, *THIS JOURNAL*, 35; 1784 (1913).

the conditions described in the method for determining the saccharogenic power.

The figures show that the amylase of *Aspergillus oryzae* resembles pancreatic amylase qualitatively in that purification does not materially change the ratio of amylolytic to saccharogenic power. Quantitatively, the ratio is much larger than that observed in the case of pancreatic amylase, in the case of which the relation remains approximately constant at about 2 : 1.

### Stability.

No systematic study was made of the stability of solutions of taka-diastase or of amylase preparations obtained from it, but the following facts have been noted during the course of the investigation:

1. A solution of Sample I stood exposed for several days during the summer to a temperature of about 32° without any decrease in activity.
2. A solution of Preparation 12d, having a power of 104 at the time it was made up, had a power of 97 after standing in a refrigerator for seventeen days.

### Summary.

The Amylase of *Aspergillus oryzae* exerts its maximum activity, both amylolytic and saccharogenic, in a very slightly acid medium. Acid phosphate accelerates, while alkaline phosphate retards, the action.

Addition of neutral electrolytes, such as sodium and potassium chloride, to commercial taka-diastase, has no measurable effect upon the saccharogenic power, but does increase the amylolytic action.

The best preparations were obtained by extracting with water, precipitating with ammonium sulfate, dialyzing, and finally precipitating fractionally with alcohol. Such preparations have about thirty times the activity of the commercial material from which they are prepared, but are not so active as purified pancreatic amylase. They have higher amylolytic, but lower saccharogenic, power than the most active malt amylase preparations yet recorded.

The high ratio of amylolytic to saccharogenic power which is characteristic of commercial taka-diastase is shown in at least equal degree by the most highly purified preparations.

The purified material resembled the preparations of pancreatic and malt amylases in most of its chemical properties. It gave typical protein reactions when submitted to the Millon, xanthoproteic, tryptophan and biuret tests. Heated in water solution it underwent coagulation, and the coagulum and filtrate both showed the biuret reaction, the color being considerably pinker in the case of the filtrate than with either the coagulum or the original material. That its nitrogen content was lower than that of the best preparations of pancreatic and malt amylases may be due either to a difference in the chemical nature of the enzyme itself,

or to the presence of other substances which the methods of purification thus far developed do not wholly remove.

### NEW BOOK.

**Qualitative Analysis.** Vol. I of Analytical Chemistry, Based on the Eighth Edition in German by F. P. TREADWELL, PH.D. (Polytechnic Institute of Zürich). Translated and Revised by WILLIAM T. HALL, S.B. (Massachusetts Inst. of Technology). 4th Ed. xiii + 538 p. New York: John Wiley & Sons, Inc. Cloth, \$3.00.

The fourth edition of this well-known text on qualitative analysis merits favorable reception as a thorough and convenient laboratory guide. Treadwell-Hall always has been a favorite text, both for the student and the practical chemist, combining, as it does, compactness with sufficient detail. It is not too unwieldy for the student who wishes to go somewhat below the surface in this subject and still covers the ground sufficiently well to meet all the usual requirements of a reference text.

The scope and volume of this edition is, in general, the same as that of previous editions. The introductory or theoretical part covers 75 pages, 117 pages are devoted to the reactions of the cations, 138 to those of the anions, 32 to systematic analysis and 64 to the reactions of the rarer elements.

In revising the book for the 4th ed. Professor Hall has rewritten, and materially added to, the theoretical portion in particular. As stated in the preface, the text is not a literal translation of the German "Treadwell" although it is kept along the same general lines, and in sympathy with the views of Professor Treadwell. Other well-known texts, as Noyes, Stieglitz, Böttger and Ostwald have been drawn upon and indebtedness to these authors is acknowledged.

The theoretical portion is furnished with valuable tables (solubility products, oxidation potentials) and examples in connection with the discussion, which is clear and to the point. The present reviewer hails with pleasure the complete adoption, in this text, of the valence method for balancing oxidation and reduction equations. While there is room for discussion, in general, of the question whether oxidation can *actually* be represented by simple electronic transfer in every case, it is obvious in many cases, and probable in the majority, that this is the actual mechanism. At all events, whoever has had occasion to fight the bug-bear of oxidation and reduction reactions on the part of students, employing long-

winded and usually absolutely hypothetical component reactions, is likely to favor the much more elegant and direct valence-method which concerns itself with nothing else than the actual changes shown. With another detail of the text, namely, the adoption of specifically coined nouns for the various ions, the reviewer cannot find himself so much in sympathy. The German language, from which this usage is copied, lends itself admirably by form and custom to the coining of compound nouns such as "chlorion" and "iodion" but the English language does not lend itself in the same manner to this process and such terms as "diferrion," "triferrion" and "chlorosion" seem exotic and confusing instead of a simplification. In part this is also due to the fact that in English the ending "ion" is so frequently used in another connection. To exaggerate, a complex ion is thus logically a "complexion;" similar confusing terms are possible. This all, is, however, only a matter of personal preference, which will be decided by custom.

More space is devoted in this text to the reactions of the "acids" than to those of the "metals," which is not the usual practice, but is a step in the right direction. This portion of qualitative analysis usually receives short shrift in most texts in comparison with the importance of the material. The writer of this believes that the preponderance of attention given to the cations is the result of tradition and the difficulty of satisfactorily treating the anions, rather than a question of importance. The classification of the acids given in the text is the one most commonly used, that of Bunsen in 1878. The amount of space devoted here to the acids is perhaps an indication that in the future a satisfactory method for the systematic separation of the acids will be included in such works. One quite satisfactory scheme has already been devised by A. A. Noyes.

The mechanical details of the book are good and misprints are few (p. 35 chloride instead of chlorate, and 4 instead of 3), the type is clear and the illustrations well gotten up.

Even the most modest chemical library will find this volume a necessary addition.

## THE PETROGRAPHIC MICROSCOPE IN ANALYSIS.<sup>1</sup>

BY F. E. WRIGHT.

Received June 26, 1916

In science, as in business, no line of research or activity is entirely isolated and self contained, free to exist by itself and for itself, but it is related to, and dependent on, other branches of scientific or business endeavor. A discovery in one particular field of investigation is not limited to that field but may have profound bearing on many other fields. Similarly a new method or a new tool devised for a special purpose in one field may serve well other purposes in another field; thus the petrographic microscope which has been developed and used chiefly by geologists can be applied with success to many chemical problems. The purpose of the present paper is to indicate briefly some of these problems and to emphasize the function of the petrographic microscope in their solution.

The petrographic microscope was introduced half a century ago by geologists because chemical and mineralogical methods failed to furnish adequate information regarding the rocks. A chemical analysis gave the bulk chemical composition of a rock but did not indicate how the

<sup>1</sup> Presented before the Washington Section, Am. Chem. Soc., on Feb. 11, 1915; the Rochester Section on March 6, 1916; the New York Section on June 9, 1916; also in abstract before the Philosophical Society of Washington on Nov. 23, 1912.

several elements were distributed among the component minerals; chemical analyses of the soluble and the insoluble portions of a rock aided to some extent, but they were not adequate to meet the requirements of petrology. To know a rock thoroughly it was essential to know not only its chemical composition but also its mineral composition and its texture as expressed in the spacial grouping of the mineral components. This knowledge was obtainable only through the aid of the petrographic microscope.

In recent years the effort has been made, especially at this laboratory, to study from the standpoint of experimental geology the conditions of formation of minerals, rocks, and ores. This implies the artificial reproduction of these minerals and rocks and their identification under the petrographic microscope. In such work the time element is a most important factor. Rocks in nature form slowly and the crystals which develop have ample opportunity to grow to a fairly large size. In the laboratory, on the other hand, time is limited, the furnace charges are small, and the resulting crystallized aggregates are very fine grained. This has of necessity led to the development of petrographic microscope methods suitable for the accurate measurement of the optical constants of crystal grains measuring only 0.01 mm in diameter. With these methods it is now possible to measure readily and with sufficient accuracy the optical constants of a substance in particles so fine that in water they settle at the rate of only 30 cm. an hour, or in air at the rate of 25 cm. a minute. As the diameter of the particles in most materials and powders exceeds 0.01 mm. ( $\frac{1}{2500}$  inch), it is evident that this downward extension of the limits, to which petrographic microscope methods can be applied, has greatly increased the range of application and usefulness of the petrographic microscope. Up to the present time, however, such methods have been used in only a few chemical problems, but in each instance they have proved to be a most effective weapon of attack for the solution of difficulties which have heretofore been considered unsurmountable.

In this connection it may be well to emphasize the fundamental difference between the petrographic microscope and the ordinary chemical or biological microscope which has been used by chemists for many decades and which is essentially a magnifier and serves to render visible minute objects and details which would otherwise escape attention. Such objects are recognized by their shape, their size, and their color. In the case of bacteria the differences in their behavior toward certain stains aid in the diagnosis, while in other lines of investigation microchemical reactions serve the same purpose. The petrographic microscope, on the other hand, is not only a magnifier but also, and essentially, an optical instrument of precision for the measurement of the optical constants of substances either in thin plates or in powder form.

To illustrate this difference between the two types of microscopes by an example: Quartz ( $\text{SiO}_2$ ) is a colorless, transparent mineral crystallizing in hexagonal prisms and pyramids of such characteristic shape that this feature alone, when present, is sufficient to establish its identity. If quartz appeared invariably in such well developed crystals, the crystal habit would suffice for its determination and the ordinary microscope would answer the purpose well; and if all substances had different and equally characteristic crystal shapes the crystal-form alone would constitute an adequate basis for distinguishing substances. But this is of course not the case, for we can destroy external crystal form by crushing the crystal into bits. Each fragment of a quartz crystal is still quartz in spite of its irregular form. Under these conditions other properties inherent in quartz itself and not dependent on its outer form must serve for the determination. The chemist naturally turns to chemical composition, melting point, boiling point, solubility, etc., which are constants and are adequate for the identification of the substance if it be available in sufficient quantity and purity for the purpose. In the case of quartz and many other minerals the determination of these properties is, however, difficult and time-consuming, while in many fine-grained mixtures of different substances these properties are not ascertainable. Under these circumstances properties must be selected which can be determined on each crystal fragment, and these are preëminently the optical properties, which serve to distinguish with certainty between different substances, especially crystallized substances.

In a crystal the component atoms are arranged in orderly fashion as the result, during crystallization, of the action of the interatomic forces. These forces are different in different directions and are vectorial and polar in character; they find expression not only in crystal form but also in the vectorial behavior of a crystal toward any external system of forces, as light-wave forces, acting upon it. The physical properties of crystals vary in such definite manner with the direction that these properties and their variations serve as diagnostic features in the determination of crystallized substances. Thus on quartz fragments we can measure with the petrographic microscope the refractive indices for different wave lengths of light, the differences in refractive indices for any given wave length (birefringence), and the character and shape of the optic ellipsoid to which the several optical properties are referable. These data of measurement serve to render the determination of the fragments as quartz practically certain. It may be noted that there are only four optical properties of crystals which are ordinarily measured in determinative work and are expressed as numerical optical constants of a given substance. These are: the principal refractive indices, the principal birefringences, extinction angles, and the optic axial angle. Other optical

properties of diagnostic value, as color, absorption, pleochroism, elongation, optical character, dispersion of the optic axes, etc., are stated in more or less qualitative form.

Of these properties the refractive indices are the most important and fundamental and also the easiest to measure with the petrographic microscope. The refractive index is the ratio of the velocity of light in air to that in the given substance. The fact that different substances have different refractive indices enables us to use the refractive index as a basis for classification. For a given wave length of light a substance which crystallizes in the isometric system has only one refractive index; this index is the same for all directions in the substance and the optical surface of reference is a sphere. In other substances, as those of the hexagonal and tetragonal systems, the optical surface of reference is an ellipsoid of rotation; such crystals have two principal refractive indices. In still other crystals (orthorhombic, monoclinic, triclinic) there are three principal refractive indices and the surface of reference is a triaxial ellipsoid.

In the practical measurement of the refractive indices of the grains in a powder, the particles are immersed in liquids of known refringence and the refractive index of any given grain is compared with that of the enveloping liquid. These grains are more or less lenticular or prismatic in shape and when immersed in a drop of liquid on an object glass and placed on the microscope stage give rise to the phenomena of prismatic refraction. Under conditions of oblique or central illumination these phenomena are easily recognizable; and relative refringence determinations between liquid and mineral grains can be made with an accuracy of  $\pm 0.001$  under favorable conditions. This method requires a set of standard refractive liquids. A convenient set is one of mixtures so prepared that the refractive index of each successive liquid is 0.005 higher than that of the liquid preceding it.

The birefringence, another useful constant, is the difference between the principal refractive indices; it signifies a difference in the rate of transmission for plane polarized light waves vibrating along different directions in the crystal and this in turn gives rise to interference phenomena which are of value in determinative work. The strength of the birefringence of a crystal grain is estimated from its interference colors between crossed nicols. In colorless minerals like quartz the scale of interference colors is practically identical with Newton's color scale.

A birefracting mineral becomes alternately light and dark four times during a complete rotation of the microscope stage between crossed nicols. In many crystal sections these positions of darkness or extinction, as they are called, make definite angles with a crystallographic direction such as the trace of a cleavage plane. These are then called extinction angles and are a useful diagnostic feature.

A further important constant is the optic axial angle. Its measurement includes the determination of the angle between the two optic axes or binormals and also the determination of the character of the acute bisectrix, whether  $\alpha$  or  $\gamma$ , from which follows by definition the optical character, negative or positive, of the mineral. For most purposes a rough estimate of the size of the optic axial angle is sufficient.

These are the more important of the several optical phenomena which can be readily determined with the petrographic microscope on grains measuring at least 0.01 mm. in diameter. They may be used in the identification of any given substance, especially crystal grains or mixtures of different crystal fragments. In many cases the determination of only two or three of these constants is sufficient to establish the identity of a substance.

If in the field of chemistry the optical properties of all chemical compounds were known, as they are for the rock making minerals, it would be an easy matter for the microscopist to determine any given compound as such even in powder form and in the presence of other compounds. A chemical analysis in the case of mixtures may accomplish little because of the impossibility of separating the different compounds. Methods are available for estimating with the petrographic microscope the relative amounts of the different compounds which are present, and thus to make a fairly good quantitative analysis of a preparation.

In tests for homogeneity the petrographic microscope is especially valuable. By immersing the preparation in a liquid of the refractive index of the main crystal compound this compound practically disappears and any foreign material can then be detected at a glance. Solid solution can also be detected by these methods and in many instances a quantitative measure of the amount of solution in the crystal state can be obtained.

The fact that it is possible to measure accurately the optical properties of minute grains measuring only 0.01 mm. suggests at once many fields in chemistry for the application of petrographic microscope methods. Thus it may serve for the identification of chemical compounds in crystalline aggregates; it is also of value in testing the purity of a preparation, either a chemical precipitate, a drug, or other commercial product, as an abrasive, cleaning powder, tooth powder, baking powder, stones in glass, and a host of other products of similar type; in research work it is useful in the study of the phase relations in two, three, and polycomponent systems. For a given composition the primary phase is determined by chilling the preparation heated to a definite high temperature and examining the quenched product under the microscope. Measurements of the refractive indices of glasses of different composition in a given system enable the observer to trace step by step the change in the composi-

tion of the liquidus as crystallization proceeds and the final eutectic is approached. By thus combining thermal, chemical, and microscopical evidence it is possible to determine the equilibrium relations in poly-component systems with a high degree of accuracy, higher in fact than is possible in metal-component systems (alloys) even though these latter are better suited for thermal study. Without the aid of the petrographic microscope the attempt to ascertain the equilibrium relations in complex silicate systems is hopeless; with its aid each one of the three-component-systems studied in this laboratory has been brought to a successful finish; the degree of accuracy of the results can be ascertained in each case.

Experience has shown that these methods are applicable to the study and identification of all nonmetallic solid substances even though present in individual grains measuring only 0.01 mm. in diameter. It requires, of course, practice to apply these methods most expeditiously. In this respect the petrographic microscope is analogous to the lathe in the machine shop. The lathe in the hands of an instrument maker is a most successful instrument and remarkable results can be accomplished with it; and yet the principles on which it is based are not difficult to grasp. Similarly the petrographic microscope is equally useful in its line and its methods are simple and easy to apply for one who has had the necessary practice. One of the most difficult features of such work is the necessity of thinking in space. The optical properties of crystals vary with the direction and the observer must picture to himself the spatial relations involved if he would understand and take advantage of the phenomena he observes. This means, of course, a certain amount of training on the part of the chemist who would utilize this tool, but the saving of time and expense thereby gained more than compensates for the labor involved. It is fortunate that in most problems the determination of the refractive indices alone suffices for the diagnosis and that the method used for such determination is extremely simple and can be learned in a few hours' time and can be accomplished with the simplest type of petrographic microscope.

To cite a few examples of the application of petrographic microscope methods to chemical problems which have come within my own experience.

#### Identification of Chemical Compounds.

**The Osazones.**<sup>1</sup>—Of the osazones there are two in the pentose sugars; four in the hexose group; 8 in the heptose, etc. Within each group the identification by chemical means is difficult and in the pentose group it may be uncertain. In view of the many optical constants which can be ascertained, it should be possible easily to distinguish between the differ-

<sup>1</sup> Samples of the pentose and hexose osazones were kindly furnished to the writer by Dr. C. S. Hudson and Dr. La Forge of the U. S. Bureau of Chemistry.

TABLE I.

Name.	Melting point.	Habit.	Elongation.	Optical orientation.	$\alpha$ .	$\gamma$ .	Birefringence.	Remarks.
<i>Penulosazones</i>								
Xylosazone	160°	needles	+	$c = \gamma$ parallel extinction	1.745	1.860	strong	Characteristic green and yellow interference colors
Arabinosazone	160	long needles	—	$c = \alpha$ parallel extinction	1.765	1.870	strong	Abnormal interference colors
<i>Hexosazones</i>								
Allosazone	175	needles	+	$c = \gamma$	1.740	1.805	strong	Characteristic blue and orange interference colors
Galactosazone	208	needles in radial groups	$\pm$	$c : \gamma = 0^\circ$ to a large angle	1.825	1.850	medium	Strong dispersion of bisectrices. No position of extinction in white light. Interference color orange and green
Glucosazone	208	needles in radial groups	$\mp$	$c : \alpha = 0^\circ$ to a large angle	1.800	1.835	medium	Abnormal interference colors, green, blue, purple
Gullosazone	168	single needles	+	$c = \gamma$	1.670	1.820	very strong	Blue, green, and yellow interference colors

ent osazones by use of the petrographic microscope, even though only a few milligrams of material be available. The optical properties of the osazones, so far as determined, are listed in Table I; the determination of these suffices for the identification of any one of the pentose or hexose osazones.

A comparison of the properties of the two pentosazones shows that both are strongly birefracting, the arabinose showing abnormal interference colors and negative elongation while xylosazone crystals show characteristic green and yellow interference colors and positive elongation. The difference in the character of elongation of the needles is a diagnostic feature sufficiently characteristic to enable the observer to distinguish between the two pentosazones at a glance on a single needle weighing a small fraction of a milligram.

The hexosazones are likewise readily distinguished by their optical properties. In the case of galactosazone and glucosazone the differences in refractive indices and in character of elongation may be used as diagnostic features. The diagnosis in this case is, however, a little less easy than it is between other osazones. In Table I the refractive indices as listed are only approximately correct, but are adequate for diagnostic purposes. Characteristic for the entire group of osazones is the strong spectral absorption in the violet and blue-violet, and consequent lemon to orange yellow color.

**The Alkaloids.**<sup>1</sup>—The determination of certain alkaloids by chemical methods is not easy and may be exceedingly difficult in the case of mixtures. It is of interest, therefore, to note that their determination by petrographic microscope methods is, so far as can be judged from the writer's limited experience with such substances, a simple matter. It should be possible to prepare a table, similar to the tables used by petrologists for rock minerals, in which the optical properties of all known alkaloids are listed; by the use of such a table the microscopist can ascertain with certainty the different alkaloids present in a crystalline mixture or the degree of purity of a particular alkaloid in the case of a drug preparation. The optical properties, so far as determined, of the several alkaloids examined, are listed in Table II. Several of the alkaloids in the list were soluble in the refractive liquid employed and their refractive indices could not be determined accurately; but the values obtained are of the proper order of magnitude and suffice for diagnostic purposes. In case more exact data are desired a new set of refractive liquids chosen with special reference to the alkaloids is required.

Certain of the alkaloids in Table II are difficult to distinguish by chemical methods, especially if present in mixtures or in small amounts; their

<sup>1</sup> Samples of the alkaloids listed in Table II were kindly furnished to the writer by Dr. C. L. Alsberg, Chief of the U. S. Bureau of Chemistry.

optical properties are so different that a correct diagnosis under the petrographic microscope is relatively easy. In view of the importance of such work, especially in cases where only small quantities are available, it would seem that a thorough study of the whole group of alkaloids from this viewpoint is advisable.

**Homogeneity Tests.**—As noted above, the testing of the purity of materials can, in many instances, be accomplished best by the petrographic microscope. Thus these methods have been used in the examination and testing of sugars, salt, flours, drugs, photographic developing powders, chemical preparations and precipitates, organic and inorganic, and of many other products.

**Analysis of Commercial Products.**—There are on the market many preparations, such as baking and cleaning powders, abrasives, paints, fertilizers,<sup>1</sup> cements, etc., which are difficult to test adequately by chemical methods alone and in which a knowledge of the actual composition as revealed by the petrographic microscope may be of assistance. To cite an illustration: in Table III are listed the approximate compositions

TABLE III.

No.	Kind.	Abrasive.		Alkali.		Soap or fat.
		Maximum diameter in mm.	Per cent.	Kind.	Per cent.	
1	Powdered quartz.....	0.3	65	sodium carbonate	25	10
2	Powdered quartz.....	0.25	85	sodium carbonate	5-10	10
3	Crushed quartz.....	0.3	75	sodium carbonate as well- crystallized sal-soda	25	..
4	Powdered alkali-feldspar (microcline), some quartz....	0.15	85	.....	..	10
5	Powdered "pumice"-obsidian, slightly vesicular.....	0.25	80	sodium carbonate	5	10
6	Powdered "pumice"-obsidian similar to 5.....	0.25	40	sodium carbonate	5	10
	Powdered quartz.....	0.25	40

				sodium bicarbonate	65	..

of eight common cleaning powders as ascertained by examination under the petrographic microscope. Many others, including soaps, etc., have been examined but the list is taken as representative of the several types. The total time taken for the examination of the eight samples was about two hours and the results listed are only first approximations sufficient

<sup>1</sup> See W. H. Fry, "Identification of Commercial Fertilizer Materials," U. S. Bureau of Soils, *Bull.* 97 (1914); also *Science*, N. S., 42, 89 (1915).

to establish the general character of the powders. In the table the optical properties of the different components are not listed, nor are certain characteristic features such as quality of crushing and sizing, purity of raw materials, etc.\* These are important and in case a given powder is to be used for a special purpose they determine in large measure its efficiency.

**Study of Equilibria Relations in Physical-Chemical Systems.**—In this laboratory petrographic microscope methods are applied primarily to the examination of the phase relations in two, three, and polycomponent systems, especially of silicates. The most detailed system yet solved is the system lime-alumina-silica.<sup>1</sup> In the course of this investigation microscopic examinations of over 5,000 heat treatments were made. The relations in this system are complicated and their elucidation required the combined attack of thermal and microscopic methods. Without the petrographic microscope the system could not have been solved; the solution was, however, of more than academic interest because of the fact that Portland cement clinker occupies a small area in one part of the diagram and the definite mineral composition of Portland cement clinker was unknown. Chemical methods alone were not competent to determine this mineral composition and it was not until after the introduction of petrographic microscope methods specially adapted to the study of fine grained preparations that we could hope for a satisfactory determination of its composition.

At present there is no text-book in which petrographic microscope methods are presented from the standpoint of this paper. Professor Chamot in his recent *Elementary Chemical Microscopy* devotes several chapters to the general description of petrographic microscope methods, but does not discuss them with reference to their applicability to fine grained materials. The writer is at present engaged in the preparation of a pamphlet in which these methods are to be presented in a form acceptable to chemists.

### Summary.

In this paper the function of the petrographic microscope as applied to certain classes of problems of a chemical nature is discussed in a general way and its usefulness in such work is emphasized. Attention is directed to the difference between the ordinary microscope which is only a magnifier and the petrographic microscope which in addition serves for the determination of the optical properties of minute crystal grains and plates measuring at least 0.01 mm. in diameter. The several optical properties thus used in diagnostic work are described briefly and the mode of their determination by means of the petrographic microscope is indicated.

<sup>1</sup> G. A. Rankin and F. E. Wright, "The Ternary System  $\text{CaO}-\text{Al}_2\text{O}_3-\text{SiO}_2$ ," *Am. J. Sci.*, [4] 39, 1-79 (1915).

The single fact that it is now possible by means of simple petrographic microscope methods to ascertain the optical constants of minute crystal grains with sufficient accuracy for diagnostic purposes suggests a number of chemical problems in which the petrographic microscope may render useful service; a few such problems are noted above. In some instances, as in Portland cement clinker and in the set cement, the actual mineral composition and the physical-chemical phase relations can be ascertained only by means of petrographic microscope methods.<sup>1</sup>

Long experience with the petrographic microscope has convinced the writer that the field of its application is a large one and full of possibilities both from the viewpoint of pure research and of practical application in the technical world; in many instances information can be obtained by means of the petrographic microscope in a few moments which it would take several days to get by the usual methods; this means an appreciable amount of time and of money saved. To know at each step in a process or investigation just what is taking place is essential to effective work and such knowledge is obtainable in many problems only with the aid of the petrographic microscope.

### DENSITY OF RADIO-LEAD FROM PURE NORWEGIAN CLEVEITE.

By T. W. RICHARDS AND C. WADSWORTH, 3D.

Received June 10, 1916.

Through the kindness of Professor Ellen Gleditsch of the University of Kristiania, we have been so fortunate as to receive a specimen of lead sulfide from carefully selected Norwegian cleveite. According to Dr. Gleditsch, "The Norwegian uraninites are very old and very unaltered. They are found in well developed crystals and occur in connection with the pegmatite dykes in southeastern Norway." The sample in question occurred in cubic crystals near Langesund.

As Hönigschmid has already pointed out,<sup>2</sup> the properties of radio-lead<sup>3</sup> obtained from pure minerals of this sort are far more interesting and significant than those of lead obtained from ordinary uranium ores, which doubtless contain some admixture of ordinary lead. Hönigschmid has shown that the lead from pure cleveite has an atomic weight as low as

<sup>3</sup> The name radio-lead is used provisionally to designate lead which appears to be the result of radioactive transformation.

206.06, and our own experience with the sample referred to above essentially confirms this result, as will be shown in another communication. So far as we know, however, the density of lead of this kind has not yet been determined, and accordingly the present paper recounts such a determination, which forms an interesting sequel to the recently published results on the density of Australian radio-lead.<sup>1</sup>

The purification of the sulfide, which doubtless contained traces of sulfides of other metals, was carried out as follows: The specimen was dissolved in nitric acid and crystallized three times with centrifuging as nitrate,—a process which Baxter's experience has shown to be an excellent one for the purification of lead from other metals.<sup>2</sup> From this purified nitrate the chloride was precipitated by pure hydrochloric acid, and this salt was crystallized three times. The final crystals, after draining on the centrifuge, were stored in a vacuum desiccator over caustic soda. The chloride thus prepared was used for the determination of the atomic weight, the density being determined in the material saved from the filtrates from that determination. These filtrates contained excess of silver, therefore enough hydrochloric acid was added to bring the concentration of the dissolved chloride ion to 0.01 normal, because at this concentration silver chloride is most nearly insoluble.<sup>3</sup> When the precipitated silver chloride had settled and had been removed by filtration through a Gooch-Munroe crucible with platinum mat, the resulting solution was concentrated and crystallized once more as nitrate. The pure crystals were electrolyzed, and the pure radio-lead treated exactly as in the case of the other samples previously described.<sup>4</sup>

The amount of substance at hand being rather small, the work could not be done quite as accurately as before. The density determinations were made in the same pycnometer as before, by the second method described on page 223,—the volume of the pycnometer having been re-determined because its tip had been broken in the meantime. Four identical determinations gave 5.7200 as the weight of water in the pycnometer at 19.94°, weighed in air. Therefore, the volume of the pycnometer was 5.7361 cc.

TABLE.—DENSITY OF LEAD FROM CLEVEITE.

<sup>4</sup> *Loc. cit.*, p. 224.

The density of this sample, presumably a nearly pure isotope, is thus 11.273, distinctly less than 11.289, the density of the Australian radio-lead, and still less than the density 11.337 found for ordinary lead. The decrease is almost exactly proportional to the decrease of the atomic weight in these samples, for the atomic weight of the Australian lead was about 206.35, and that of this sample 206.085. Thus the atomic volume of the isotope  $((206.08)/(11.273) = 18.281)$ , is almost identical with that of pure lead, as indicated by our previous experiments. 18.281 is essentially equal, within the limit of error of experiment, to the value 18.277, found for ordinary lead, and to the value 18.279, found for Australian radio-lead. It is interesting to note that Australian radio-lead would be essentially duplicated as to these properties by a mixture consisting of three parts of pure isotope to one of ordinary lead.

### Summary.

This brief paper describes the determination of the density of lead from Norwegian cleveite kindly furnished by Professor Gleditsch. This lead, presumably a pure isotope, was found to have a density (11.273) decidedly lower than the mixture previously studied. The corresponding atomic volume of the pure isotope is essentially equal to that of ordinary lead, as indicated by the earlier results on radio-lead from Australia.

## AN ELECTRO-ANALYTICAL METHOD FOR THE DETERMINATION AND SEPARATION OF THE METALS OF THE COPPER-TIN GROUP.<sup>1</sup>

BY EUGENE P. SCHOCH AND DENTON J. BROWN.

Partly in collaboration with THOMAS E. PHIPPS.<sup>2</sup>

Received May 6, 1916.

Solutions containing chlorides have been considered unsuitable for the electro-analytical deposition of metals, probably on account of the oxidizing action of the liberated chlorine. Since the formation of chlorine can be prevented by the addition of reducing agents, and since such solutions present all the advantages of *simple acid electrolytes* while they are more serviceable than either the "sulfuric acid" or the "nitric acid" electrolytes advocated by Foerster<sup>3</sup> and by Sand,<sup>4</sup> respectively, it was decided to investigate their use with the more common metals, particularly with

<sup>1</sup> This work was carried out at the University of Texas under the direction of Professor Schoch and presented to the University of Chicago by Mr. Brown as part of the dissertation in partial fulfillment of the requirements for the Ph.D. degree.

<sup>2</sup> Mr. Thomas E. Phipps worked out the methods given in Arts. 13, 14, 15, and 16.

bismuth, antimony, and tin. For antimony and tin the only method known heretofore which uses an acid electrolyte is that devised by Sand<sup>1</sup> and it requires the use of fairly concentrated sulfuric acid (sp. gr. 1.4), a temperature above 100°, and is altogether not as practicable or convenient a method as may be desired.

We have found that antimony, bismuth, copper, lead, tin and cadmium may be deposited quantitatively and in good form from "hydrochloric acid" electrolytes if suitable reducing agents are present in the solutions and oxides of nitrogen or nitric acid are absolutely absent; and that these electrolytes admit of the separation of all these metals from each other and from such other metals of the copper-tin group as would, if present, have to be considered.

### Apparatus and Manipulations.

**The Electrolytic Apparatus.**—In all of our work we used the Sand-Fischer apparatus and electrodes.<sup>1</sup>

The figure on p. 1661 presents the apparatus in detail. The introduction of a clamp of a special design made it possible to remove and replace quickly either of the two concentric electrodes without disturbing the other. This method of clamping eliminated the very undesirable glass tube formerly used for insulating the stem of the cathode, holds the electrodes more rigidly, and renders it possible to keep the electrodes suspended above the bottom of the beaker, thus permitting of more efficient stirring than is possible with the electrodes resting on the bottom. The electrodes were made of a fine platinum wire gauze—about 25 meshes to the cm. with a wire 0.1 mm. in diameter. The total surface of the cathode (or outer gauze cylinder) was estimated to be about 90 sq. cm. Hence the absolute values of the currents used are also very nearly the values of the current densities per 100 sq. cm. The most suitable beaker for the electrolyzing vessel was found to be a very tall or narrow beaker of 350 cc. capacity (height, 12½ cm.). With this beaker, the volume of electrolyte necessary to cover the electrodes is about 150 cc. The platinum anodes or cathodes were constantly reweighed during the progress of this work, and none of them decreased in weight during the operations mentioned in this paper.

The normal calomel electrode was employed as the auxiliary electrode in all of our determinations.

**Special Remarks on Manipulation.**—In the determination of metals that form alloys with platinum, *e. g.*, tin, lead and antimony, the platinum cathode was always covered with a deposit of copper before depositing the metal.<sup>2</sup>

Energetic stirring is essential to the success of these electro-analytical operations. Our stirrer made 800 revolutions per minute, but our apparatus was so rigid and the beaker so high that no loss through splashing was experienced. The sides of the beaker and the stirrer were always washed with a stream of water a short while before the end of a determination.

<sup>1</sup> For a general description of the apparatus and methods of determination by "graded potential" see texts on electroanalysis, *e. g.*, Smith, *Electroanalysis*, 274-84; Classen (translated by Hall), *Quantitative Analysis by Electrolysis*, Part I; Fisher, *Electroanalytische Schnellmethoden*. The apparatus we used was made by F. Koehler, Leipzig, Germany.

<sup>2</sup> If the deposit of copper is too thin, these metals pass through and unite with the platinum electrode. In such cases the general treatment for the removal of metal deposits will fail to remove all of the deposit. A remnant of antimony could be removed by heating the electrode to whiteness without loss of weight to the platinum electrode, but tin and lead cannot be removed by this method.

It was observed that all of our metal deposits, when covered by a film of the electrolyte, oxidize quickly on exposure to the air. Hence a special effort was made to remove the electrolyte quickly and effectively from the cathode. If the electrolyte was to be employed for the determination of a second metal, the deposit was washed with a stream of water while the beaker was lowered away from the electrodes. If no other quantitative determination was to be made, a beaker of distilled water was quickly substituted for the electrolyte. The deposit was then washed successively in alcohol and in ether and finally dried by holding it high above a Bunsen burner flame.

All metal deposits, except those of antimony and tin, can be removed by means of nitric acid, but antimony and tin form oxides which adhere so tenaciously to the electrodes that they require the use of a brush to remove them. Hence these metals were removed electrolytically by connecting the electrode with the deposit as an anode in dilute hydrochloric acid. Antimony can also be removed by means of a mixture of nitric and tartaric acids. Lead peroxide is removed by means of a mixture of nitric and oxalic acids.

All metal deposits can be removed by immersing them in a mixture of concentrated hydrochloric acid and water (1 : 1), adding nitric acid—a few drops at a time—and proceeding as directed below under “Preparation of Electrolyte.” This method of redissolving metal deposits was employed particularly for dissolving mixtures which required further separation.

**Préparation of Electrolyte.**—As the determination of very small amounts of any metal to be deposited is in reality the same as the determination of the last portions of larger amounts, no special determinations were made with minute quantities of metals, and the samples were all chosen so as to contain, of the metals to be deposited, the largest amounts suitable for these determinations. Whenever other metals than those to be deposited were added, they were also added in the largest proportion in which they are ever likely to be present in a practical analysis, because the probability that the deposited metal may be contaminated by other metals becomes greater as the amounts of such other metals in the electrolyte becomes greater.

The purity of the substances used for samples was always ascertained by the usual qualitative tests, in addition to the careful observation of the quantitative results attained. When pure metals were not obtainable for samples, they were either prepared electrolytically—as in the case of bismuth—or some pure definite compound of the metal was used, *e. g.*, antimony oxide, recrystallized arsenious oxide, etc.

We weighed out as much of the sample as would give a deposit of at least a tenth of a gram of any constituent, but would not give a total for

any single deposit greater than two-thirds of a gram. To this we added 8–12 cc. of concentrated hydrochloric acid (sp. gr. 1.20) and an equal amount of water. Samples consisting of tin or of more reactive metals were placed in contact with platinum, under which conditions they dissolve rapidly, but if lead or metals more noble than lead were present, we added a few drops of nitric acid, not sufficient to react with the whole sample, and warmed the mixture slightly—not above  $75^{\circ}$ —in order to prevent the loss of volatile chlorides. Since it is very essential that the mixture is not overheated—even momentarily—we placed the beaker in a water bath kept at about  $70^{\circ}$  or we placed it inside of a larger beaker containing some water warmed to  $70^{\circ}$ . When the reaction ceased, we added more nitric acid, a drop at a time, and allowed each portion to react completely before adding the next one; this we continued until the whole sample had been attacked with the least possible amount of nitric acid. An excess of nitric acid is to be avoided because it will prevent the complete deposition of the metals, and can not be removed completely even by the addition of such active reducing agents as hydrazine or hydroxylamine hydrochloride. Its removal by evaporation is generally not practicable because the chlorides of several metals of this group are volatile, *e. g.*, the chlorides of arsenic, antimony and tin.

Next we added 2 g. of hydroxylamine hydrochloride (to remove the oxides of nitrogen and the free chlorine), and heated the mixture as before, not to exceed  $70^{\circ}$ . The mixture was then diluted to 150–200 cc. to suit the size of the electrolytic vessel, and electrolyzed according to the methods presented below. Some of the experimental work was done with solutions prepared in ways different from the above. Special mention will be made of this fact wherever that was the case.

### **The Systematic Separation of the Metals of the Copper-Tin Group.**

The ultimate object of this investigation is the devising of a system for the electro-analytical separation and determination of all the common metals. The work in this paper together with some well-known analytical facts has practically enabled us to attain this object; and since the data to be presented in this paper owe a large part of their value to the fact that they fit into such a scheme, we have decided to present an outline of such a scheme here. The outline will show the relation of the different experimental results to each other and to the whole.

If arsenic is present, the sample should be dissolved as outlined above, somewhat more hydroxylamine hydrochloride (a total of 3 g.) should be added, the concentrated mixture should be transferred to a 200 cc. distilling flask (with the aid of concentrated hydrochloric acid to “wash” the remnants into the flask, or better, the whole previous treatment is made in this flask), and the arsenious chloride is distilled while a current of hydrogen chloride gas is passed through the distilling flask (Fischer's

method).<sup>1</sup> The distillation should be continued until the residue in the distilling flask has a volume of 10 to 20 cc. It should be mentioned here that if antimony is present, a small amount of antimonous chloride may distil over, and will be determined together with arsenic if the latter is determined by titration with iodine; but this trace of antimony can be conveniently separated from the arsenic by Bunsen's method<sup>2</sup> and determined, or added to the residue left after distillation.

If the residue left in the distilling flask is less than the original volume (20 to 25 cc.), it should be brought up to this volume by the addition of a mixture of equal parts of water and concentrated hydrochloric acid.

The residue from the arsenic distillation is rinsed into an electrolysis beaker, and is then diluted as necessary for electrolysis. Of course, if arsenic is not present, the original concentrated solution is thus diluted. If a precipitate of mercurous chloride, of silver chloride, of gold or of platinum is present, the concentrated mixture should be diluted only partially, filtered, the precipitate washed, and the filtrate plus the washings diluted further until the solution has the volume necessary for electrolysis (150-200 cc.).

If the precipitate on the filter paper contains silver chloride, it should be treated with ammonia. Silver may be deposited quantitatively out of this solution in ammonia by a method elaborated recently in this laboratory, and presented under a separate heading at the end of this paper.

Any mercurous chloride, gold or platinum remaining on the filter may be separated and determined by well-known methods.

From the solution obtained as above described, the first metals to be deposited with the least electromotive force, will be bismuth, copper or antimony. These three metals are deposited under practically the same conditions; hence, if more than one of them is present in the electrolyte, they will be deposited together according to the directions given in Sections 13, 12, 11, 6, 5, 4, 3 or 2. The first section here mentioned presents the general method in its final form, usable with all metals present, while the other sections present the general method in the earlier form, or methods usable when only certain metals are present. These metals may be separated by methods given in Sections 16, 15, 14 or 10.

After the removal of the above metals, the next metals to be deposited from the electrolyte are tin and lead. These metals are deposited under practically the same conditions; hence will be deposited together if both

<sup>1</sup> This procedure was tested quantitatively in this laboratory by Mr. R. M. King. The apparatus and procedure employed is essentially identical with that recently published in *J. Ind. Eng. Chem.*, 8, 329 (1916), except that we passed a current of hydrochloric acid gas through the apparatus, while the directions in this reference call for the addition of concentrated hydrochloric acid. The latter probably makes the operation more convenient.

<sup>2</sup> See Classen, *Quantitative Analysis* (translated by Harriman) ed. 1902, p. 89.

are present in the electrolyte. For details see Sections 9, 7 or 1. This alloy is readily separated by the method in Section 8.

Cadmium is the last metal in this list to be deposited from the electrolyte after the removal of the metals above. No metals "more zincic" than cadmium are considered in this outline. The term "more zincic" is employed, in preference to "more negative," to signify that the element is more active as a metal, or has a greater tendency to form positive ions—"more like zinc."

Since the relations of the facts presented in this paper are shown by the outline, it is unnecessary to indicate them again; hence we will present our results in the order in which they were obtained rather than in the order which would conform to the outline. A list of the different determinations—or section headings—is given here for convenient reference.

1. (a) **The Determination of Tin: General Method.**—Copper plated cathodes were used for all depositions of tin.

Preliminary experiments showed that in the absence of reducing agents the greater part of the tin present in a solution of stannous chloride acidified with hydrochloric acid can be deposited rapidly in excellent form, but that the remnant could not be deposited even when the current was increased or continued for a long time. In fact, the tin finally dissolved more rapidly than it was deposited, until all the tin was redissolved. This was undoubtedly due to the high concentration of chlorine in the solution after long electrolysis, because when a suitable reducing agent

is present in the electrolyte, the tin is deposited quantitatively. These trials indicate that chlorine is the main cause why many metals cannot be deposited completely from chloride electrolytes.

In the following determinations "Analyzed" pure tin was dissolved cold, in approximately 10 cc. of hydrochloric acid, sp. gr. 1.20, in contact with metallic platinum. After the addition of the reducing agent, the resulting solution was diluted to approximately 200 cc. and electrolyzed.

The maximum current density, with which a good deposit of tin may be obtained out of the "hydrochloric acid" electrolyte, *decreases* as the concentration of the tin salt *increases*. With amounts of tin as high as 0.7 g. in 200 cc., a current of 1.5 amperes gave, with the electrodes employed, a good deposit at temperatures ranging from 30 to 70°. With higher current densities, the relatively concentrated solutions gave granular deposits, and even "trees," but less concentrated solutions gave good deposits even with somewhat higher current densities. Since 0.7 g. would be as large an amount of tin as would be used ordinarily for analysis, and as 1.5 amperes may be safely used with this concentration of 0.7 g. in 200 cc., this amount of current was used at the start in all the determinations of tin.

The "end point" was determined by ascertaining whether or not an increase in the weight of the deposit was obtained upon replacing the electrode in the electrolyte, and electrolyzing further. The result was also confirmed by qualitative tests.

TABLE I.

Reducing agent.		Time. Minutes.	Tin.

		75	0.3830	0.3822	—0.22
		85	0.2070	0.2064	—0.29

A comparison of the results obtained with these and other reducing agents is of special interest. With hydroxylamine hydrochloride, tin is deposited completely and in a comparatively short period of time. With oxalic acid, a trace of tin always remains in the electrolyte, that is, the tin is deposited almost, but not quite, completely. With formaldehyde the deposition is decidedly incomplete, though more extensive than would be the case if no reducing agent were employed. The fact that with formaldehyde the deposition is incomplete is rather surprising because, in some respects, formaldehyde is a stronger reducing agent than hydroxylamine; but this anomaly may be due to the fact that formaldehyde acts as an

oxidizing agent towards energetic reducing agents; hence perhaps toward stannous chloride.

1. (b) **A Modification of Classen's Ammonium Oxalate Methods for the Determination of Tin.**—It is well known that tin may be completely deposited out of a solution to which both ammonium oxalate and oxalic acid have been added. However, the oxalate methods heretofore employed have some undesirable features: the procedure recommended by Classen<sup>1</sup> gives an excellent deposit, but requires a long period of time (nine hours); while Exner's<sup>2</sup> rapid method requires the use of a "hot saturated" solution of ammonium oxalate, which is somewhat troublesome to handle, and the deposit is loosely adherent and powdery. Hence an improvement of the "oxalate method" is desirable. Since we found that the maximum current density with which a good deposit may be obtained from Classen's oxalate electrolyte increases as the concentration of the tin decreases, we concluded to combine this fact with the fact stated at the beginning of the determination of tin, namely, that even in the absence of a reducing agent tin may be deposited almost completely from a chloride electrolyte. The new "oxalate method" thus devised is carried out as follows: The greater part of the tin is deposited rapidly out of the simple "hydrochloric acid electrolyte to which no reducing agent has been added;" then the ammonium oxalate and oxalic acid are added and the remnant of the tin is deposited fairly rapidly. A current of 1.5 amperes may be used during the whole determination. "Time I" in the table below shows the number of minutes during which the original "hydrochloric acid" solution was electrolyzed and "Time II" the number of minutes during which the solution was electrolyzed after the ammonium oxalate and oxalic acid have been added. The modification places this "oxalate method" in the list of "rapid methods."

TABLE II.

4	10	45	30	75	0.2608	0.2606	—0.08

2. **The Determination of Copper.**—It is impossible to deposit copper in good condition from a simple solution of cupric chloride acidified with

<sup>1</sup> See Classen-Hall, "Quantitative Analysis by Electrolysis," 1913, p. 136.

<sup>2</sup> See Smith, "Electroanalysis," 1907, p. 168.

hydrochloric acid, but in the presence of suitable reducing agents copper can be deposited quantitatively and in excellent form, provided the concentration of the copper does not exceed 0.4 g. per 100 cc.—which is from 0.6 to 0.8 g. for the usual volume employed—with greater concentrations of copper, no electrolytic deposit is obtained.

The "most zincic" cathode potential with which copper could be obtained in good form is approximately  $-0.60$  volt against the "normal calomel electrode." This is practically the potential at which hydrogen is evolved from this electrolyte on copper; hence the appearance of hydrogen may be used to limit the applied voltage. The determinations below marked "hydrogen limit" have been made in this way, that is, by keeping the current or voltage just low enough to avoid the evolution of hydrogen. The least "zincic" cathode potential with which copper may be practically completely deposited is  $-0.40$  volts against the calomel electrode, but frequently 0.1 to 0.3% of copper cannot be deposited at this potential and in general complete deposition is secured only with a cathode potential of  $-0.50$  volt. This potential just barely admits of the separation of copper from tin or lead. Naturally, when the cathode potential is limited at any value between  $-0.50$  and  $-0.40$  volt, the deposit of copper is certain to be free from tin or lead, but a few tenths per cent. of copper may not be deposited.

Metals more "zincic" than tin or lead are kept out of the copper deposit by not allowing the cathode potential to become more zincic than  $-0.60$  volt or by keeping the potential below that with which hydrogen begins to be evolved.

The salts of none of these "more zincic" metals, except those of iron, exert any specific effect; but iron salts prevent the deposition of copper, unless hydroxylamine hydrochloride is employed as the reducing agent.

In connection with the selection of suitable reducing agents for copper, we found that a weak reducing agent such as tartaric acid could be used for its separation from cadmium, nickel, cobalt, chromium and manganese, but that more time is required when this reducing agent is employed than when one of the more active reducing agents, such as formaldehyde or hydroxylamine hydrochloride, is employed. Hydroxylamine hydrochloride is really the only reducing agent that gave good results under all conditions; hence we have used it rather generally.

Special attention is here called to the fact that the behavior of the cathode potential during the deposition of a metal furnishes the operator a reliable automatic indication of the "end point." As the amount of the metal ion in the solution decreases and finally becomes zero, it is necessary to reduce the applied voltage so that the current finally reaches a low "residual" value, or becomes practically zero. In our work the "end points" were all ascertained in this way, which accounts for the differences in the re-

quired lengths of time given in the table of results below. We note that the minimum lengths of time for the determination of copper were required when hydroxylamine hydrochloride was employed, which is another reason why we believe that this is the most suitable reducing agent for these determinations.

Sometimes copper will not begin to be deposited immediately when the current is turned on. This is usually due to the fact that too much nitric acid has been used in dissolving the sample. Occasionally the disturbing factors are removed by the passage of the electric current, but generally the trouble is irremediable. This is true not only for the deposition of copper but for the determination of other metals.

The solution usually becomes clear long before the copper is completely deposited; this is due to the conversion of the cupric salt to cuprous salt, and should not mislead the experimenter into believing that the copper is nearly all deposited. A qualitative test for copper should not be attempted for a long time after the blue color has disappeared, because the liquid removed for testing cannot be returned to the electrolyte.

Pure electrolytic copper was used for the determinations below. The electrolyte was prepared by the general method described above. Besides hydroxylamine hydrochloride, various other reducing agents were used with copper, as the experiments show.

**3. The Separation of Copper from Tin.**—Weighed amounts of copper and tin were dissolved and the electrolyte was prepared according to the general directions given at the beginning of this paper. Special care was taken to avoid an excess of nitric acid, and to avoid heating the solution above  $75^{\circ}$ , or it was found impossible to recover all of the dissolved metals.

The copper was deposited by limiting the cathode potential to  $-0.40$  volt against the "normal calomel electrode." The cathode was weighed, replaced in the solution, two grams additional of hydroxylamine hydrochloride were added, and the tin was deposited in accordance with the directions given for depositing tin. The following results were obtained:

TABLE IV.

Copper.			Tin.		
Present.	Found.	Error. %.	Present.	Found.	Error. %.
0.5165	0.5165	0.00	0.6126	0.6147	+0.34
0.4502	0.4482	-0.42	0.3148	0.3162	+0.42
0.3334	0.3344	+0.30	0.2124	0.2120	-0.20
0.5002	0.5004	+0.04	0.5002	0.5008	+0.12
0.5002	0.5006	+0.08	0.5860	0.5858	-0.03

Some of our students secured excellent results when they limited the cathode potential to  $-0.50$  volt. (See also Section 2, second paragraph.) Qualitative tests were made to determine whether the separation was complete. The absence of tin in the copper deposit was shown by the

absence of a precipitate of stannic oxide when the copper deposit was dissolved in nitric acid. The absence of copper in the "residual" electrolyte was shown by the "ferrocyanide test." Finally, after the deposition of the tin, the solutions were treated with hydrogen sulfide to ascertain whether all the tin had been deposited; no discoloration of the solution was produced by the hydrogen sulfide.

**4. The Determination of Bismuth.**—In order to obtain a good deposit of bismuth out of an electrolyte which contained hydrochloric acid and hydroxylamine hydrochloride, it was necessary to limit the potential of the cathode against the "normal calomel electrode" to  $-0.25$  volt, or less, until most of the metal had been deposited and the current had been reduced to a very small fairly constant value. Then the applied voltage was raised gradually so that the residual current was not appreciably increased, and the electrolysis continued until the potential of the cathode against the calomel electrode attained the value  $-0.5$  volt. Then the current was interrupted.

"Analyzed" pure oxychloride of bismuth was employed for the following determinations. The samples were dissolved in 5 cc. hydrochloric acid, sp. gr. 1.2, and 2 g. of hydroxylamine hydrochloride were then added. The solution was diluted to 200 cc., heated to  $55-75^{\circ}$  and subjected to electrolysis in the manner stated before.

TABLE V.

BiOCl.	Bismuth.		Error. %.
	Present.	Found.	
0.4938	0.3958	0.3954	$-0.10$
0.4049	0.3245	0.3247	$+0.06$
0.3930	0.3150	0.3150	$-0.00$
0.4298	0.3445	0.3442	$-0.09$
0.4551	0.3648	0.3646	$-0.06$

**5. The Determination of Antimony.**—Several peculiar properties of antimony and its salts must be considered in connection with its electrolytic determination. If hydrogen is evolved during the electrodeposition of the metal, some of the latter will escape in the form of stibine. If the electrodeposition takes place below  $50^{\circ}$ , the impure "explosive" antimony is deposited;<sup>1</sup> while above  $70^{\circ}$  the tendency of the antimony chloride solutions to hydrolyze increases rapidly with increase of temperature, and antimony chloride will be lost by volatilization. Our electrolytic method was designed to avoid all these sources of error.

Weighed samples of antimonous oxide,  $Sb_2O_3$ , "Analyzed" were treated with 20 cc. of hydrochloric acid, sp. gr. 1.20 (more than is used for other metals—on account of the hydrolyzing tendency of the antimony), and with 2 g. of hydroxylamine hydrochloride. The resulting solution was

<sup>1</sup> *Z. physik. Chem.*, **52**, 129 (1905).

diluted to 200 cc. The dilution of any solution containing antimony chloride must always be made very quickly while stirring, in order to prevent hydrolysis. The electrolyte was heated to a temperature between 50 and 75° and deposited on copper-plated electrodes with a cathode potential of  $-0.30$  to  $-0.40$  volt against the normal calomel electrode until the current dropped to "zero." The following results were obtained

TABLE VI.

Time.	$Sb_2O_3$ .	Antimony.		Error. %.

**6. The Separation of Antimony (or Bismuth) from Tin.**—The sample was prepared as previously stated, except that 15 cc. of concentrated hydrochloric acid were employed (to prevent the hydrolysis of the antimony salts), and 4 g. hydroxylamine hydrochloride were added. The solution was diluted to 200 cc., heated to 50°, and electrolyzed with the cathode potential at  $-0.40$  volt until the current reached a constant minimum which indicated that the deposition of the antimony was complete.

TABLE VII.

0.4457	0.4444	$-0.29$	0.4948	0.4926	$-0.44$
0.2105	0.2006	$+0.05$	0.2846	0.2838	$-0.29$
0.3945	0.3946	$+0.03$	0.6578	0.6580	$+0.03$

This is evidently to be preferred to the tedious gravimetric separation of these two metals.

Since bismuth may be deposited out of the same electrolytes at a potential slightly "less zincic" than that required for antimony, the separation of bismuth from tin can undoubtedly be effected under the same general conditions given for the determination of bismuth. As much of this metal as possible must be deposited while the cathode potential is limited to  $-0.25$  volt, or less, against the calomel electrode; then the applied voltage is to be raised, without increasing the residual current, until the cathode potential has attained the value  $-0.40$  volt.

**7. The Determination of Lead.**—Copper-plated electrodes were used for all lead deposits.

Weighed quantities of "Analyzed" lead chloride were dissolved in 200 cc. of hot water to which 10 cc. of concentrated hydrochloric acid had been added. The reducing agent was added and the solution electrolyzed while warm (60–70°) with a current of 1.5 amperes for 25 or 40 minutes. The "end point" was determined as with tin—by replacing the weighed electrode in the electrolyte, electrolyzing further, and weighing the electrode again. The solution was also treated with hydrogen sulfide to prove the absence of lead. The following results were obtained:

TABLE VIII.

Reducing agent employed.	Amount of lead chloride.	Lead.		Error. %
		Present.	Found.

	0.3462	0.2579	0.2580	+0.04
	0.3746	0.2792	0.2790	—0.07
Formalin.....	0.2734	0.2036	0.2038	+0.10
	0.3282	0.2444	0.2438	+0.16
	0.3042	0.2265	0.2262	—0.13
	0.3036	0.2260	0.2258	—0.09

These results are more reliable than those obtained by depositing lead as a peroxide.<sup>1</sup> One remarkable feature of this deposition of lead is that formaldehyde may be employed while it cannot be employed in the deposition of tin. The difference may be due to the fact that the lead chloride, unlike stannous chloride, is not an active reducing agent.

### 8. The Simultaneous Deposition of Lead and Tin and Their Separation.

—The potentials at which tin and lead are deposited from acidified chloride solutions are so close together that an electrolytic separation is impossible. On this account, and because these metals alloy readily, they are deposited together under the same conditions under which either one is deposited; hence both together may be separated from other metals just as either one alone may be deposited. This leaves us merely the special problem of their separation.

When an alloy of tin and lead is treated with nitric acid, the insoluble stannic oxide adsorbs some of the lead salt; hence the separation is incomplete. It occurred to us that it might be possible to find a salt which would be adsorbed more readily than the lead nitrate, and which, if added to the mixture, would allow the lead salt to be released. When potassium nitrate is added to the nitric acid a complete separation of tin and lead is effected. The lead may be deposited as peroxide from one of the two separate portions thus obtained; and the tin may either be obtained by difference, or it may be determined by treating the insoluble stannic

<sup>1</sup> Sand, *Faraday Society*, 5, 210.

oxide with concentrated hydrochloric acid and hydroxylamine hydrochloride, and depositing the tin by electrolysis.

This separation was carried out according to two slightly different methods of procedure. In the first, the mixture of tin and lead was treated with nitric acid in the usual manner, the mixture was heated until all nitrous oxide fumes were expelled, diluted to 200 cc., boiled, stirred for ten minutes with the stirrer of the electrolytic apparatus and filtered. The impure precipitate was washed back into the beaker, 10 g. potassium nitrate were added, the mixture was boiled, stirred and filtered as above. The lead in the filtrate was determined by electrodeposition on the anode as lead dioxide. The stannic oxide was immediately treated with concentrated hydrochloric acid in presence of hydroxylamine hydrochloride, and the tin deposited from the resulting solution by our method.

TABLE IX.

Lead.			Error. %.	Tin.		Error. %.
Present.	PbO <sub>2</sub> .	Found.		Present.	Found.	
0.3886	0.4474	0.3874	-0.31	0.6644	0.6636	-0.12
0.5050	0.5828	0.5047	-0.06	0.7850	0.7846	-0.05
0.5546	0.6394	0.5537	-0.16	0.3452	0.3452	0.00

In the second method, the mixture of tin and lead was dissolved in 10 cc. of concentrated nitric acid in the presence of 10 g. of potassium nitrate dissolved in 40 cc. of water. The mixture was heated as before to expel the nitric oxide fumes, diluted to 200 cc., boiled, stirred for fifteen minutes with the stirring apparatus used for the deposition, cooled, filtered and washed. The tin and the lead were then determined as stated above.

TABLE X.

Lead.			Error. %.	Tin.		Error. %.
Present.	PbO <sub>2</sub> .	Found.		Present.	Found.	
0.4718	0.5462	0.4730	+0.25	0.4310	0.4310	0.00
0.4074	0.4710	0.4079	+0.12	0.4414	0.4422	+0.18
0.3052	0.3520	0.3048	-0.13	0.5126	0.5130	+0.08

In addition to the above quantitative separation, a qualitative test was made to show that none of the lead salt remained in the stannic oxide. The precipitate was dissolved in a mixture of concentrated hydrochloric acid and hydroxylamine hydrochloride, then diluted and treated with hydrogen sulfide, and the precipitate treated with yellow ammonium sulfide; it dissolved completely.

**9. The Separation of Tin from Cadmium.**—Mixtures containing known amounts of stannous and cadmium chlorides were prepared by measuring out portions of solutions of known concentrations of these salts. Sufficient hydrochloric acid was added to prevent hydrolysis, 2 g. of hydroxylamine hydrochloride were added, and the requisite amount of water to bring the volume to 200 cc. With the solution warmed to 70°, the tin was deposited

by limiting the current to 1.5 amperes until the cathode potential had attained the value  $-0.70$  volt against the "normal calomel electrode." Then the current was reduced in order to keep the cathode potential constant until the current attained a constant "residual" value. The tin was found to have been completely deposited. After weighing, the cathode was replaced, the applied electromotive force was raised until a current of one ampere passed (higher currents gave spongy deposits of cadmium), and this current was continued until a qualitative test showed the absence of cadmium. About forty to sixty minutes were required to complete the deposition of the cadmium.

TABLE XI.

Tin.		Error. %.	Cadmium.		Error. %.
Present.	Found.		Present.	Found.	
0.4710	0.4710	0.00	0.3010	0.3010	0.00
0.4710	0.4712	+0.05	0.3010	0.2994	-0.50
0.4710	0.4710	0.00	0.3040	0.3048	+0.26
0.4710	0.4700	-0.22	0.3010	0.3006	-0.13

No trial was made to separate lead, or lead and tin, from cadmium, but from our point of view no reason can be seen why the separation could not be accomplished in the same way as the separation of tin from cadmium.

**10. The Separation of Copper from Antimony by Means of Hydrochloric-Tartaric Acid Electrolytes.**—Copper and antimony were dissolved as usual in hydrochloric acid with the minimum amount of nitric acid. Then 8-10 g. of tartaric acid were added, the mixture was diluted and electrolyzed. The electrolyte was kept cool, not to exceed  $25^{\circ}$ , because at higher temperatures greater potentials are required to deposit the copper completely out of acidified tartrate electrolytes, and the separation of copper from antimony becomes impossible. A current of two amperes was allowed to pass until the "observed cathode potential" had attained the value  $-0.50$  volt; then the current was reduced so as to keep the "cathode potential" constant at  $-0.50$ ; when the current had become practically zero, the applied voltage was kept constant until the cathode potential rose to  $-0.65$  volt; then the experiment was terminated. Of course, this separation can be made with lower potentials, but not as rapidly.

Copper.		Error. %.	Copper.		Error. %.
Present.	Found.		Present.	Found.	
0.3596	0.3604	+0.22	0.3444	0.3442	-0.06
0.4424	0.4432	+0.18	0.4582	0.4588	+0.13
0.4782	0.4778	-0.08	0.5790	0.5788	-0.03

As the deposit was excellent in color and the remaining electrolyte gave no indication of copper with the ferrocyanide test, the separation was considered to be quantitative. No reliable method is known for

depositing the antimony out of tartrate solution; we found that only a portion of the antimony could be deposited.

**11. The Separation of Copper and Antimony from Lead by the General Method and the Separation of Copper from Antimony by means of Nitric-Tartaric Acid Electrolytes.**—In this procedure we separated copper and antimony from lead by depositing the first-mentioned two metals together. We did not make the corresponding separation of copper and antimony together from tin because the similarity in the properties of these metals indicates that this separation can be carried out by the method given under this heading—an idea that is confirmed by the results given in Section 13.

Weighed quantities of copper, antimony and lead were dissolved in the usual manner, except that 20 cc. of concentrated hydrochloric acid were used in place of 10 cc. to prevent hydrolysis of the antimony salts. To this mixture, 2 g. hydrazine hydrochloride were added, the mixture was diluted slightly and heated slowly to 60° with constant stirring. There was an evolution of gas, which was probably due to the action of the hydrazine on the nitrous oxides. Then the solution was diluted while hot, to 200 cc. and electrolyzed with a copper plated cathode. The copper and antimony were deposited together by limiting the cathode potential to  $-0.40$  volt against the normal calomel electrode until the current fell to a tenth of an ampere; then the applied voltage was kept constant until the cathode potential against the auxiliary electrode was  $-0.50$ . The electrode with the deposit of copper and antimony was weighed and the deposit was dissolved in diluted nitric acid in the presence of 10 g. of tartaric acid. Then the copper was deposited with the cathode potential limited to  $-0.30$  volt, and the temperature limited to 20°. The copper deposit had an excellent appearance. The weight of the antimony was obtained by subtracting the weight of the second deposit from the first. The lead, still in the first electrolyte, was deposited on a copper plated cathode.

TABLE XII.

**12. The Simultaneous Deposition of Antimony, Bismuth and Copper out of Electrolytes Containing These Metals and Tin.**—The first three were separated from tin by depositing them together according to the directions given for the determination of bismuth, Section 4.

Bi + Cu + Sb.		Error. %.
Present.	Found.	
1.0930	1.0922	-0.08
0.9370	0.9380	+0.11

The separation of these metals from solutions containing both lead and tin has been accomplished by the same method as that here employed (see Section 13).

In the separation of antimony, bismuth and copper from tin, it was noted that bismuth always came out first; in other words, bismuth is deposited from acid chloride solutions at a lower "cathode potential" than either copper or antimony, hence should be placed lower in the electro-motive series than copper, while antimony should be placed above copper. However, the deposition potential of bismuth is so near to that of copper that it was found impossible to separate it from the latter out of these electrolytes.

**13. The Simultaneous Deposition of Copper, Bismuth and Antimony out of Electrolytes Containing These and also Lead and Tin.**—Samples of weighed quantities of copper, of bismuth oxychloride, and of antimony oxide, and unweighed quantities of lead and tin were dissolved according to the usual procedure. When lead chloride was present in relatively large amounts, the crystals of this substance were removed by filtration. The copper, bismuth and antimony were deposited by the method given for the determination of bismuth, except that it was found necessary to limit the cathode potential to  $-0.20$  volt against the normal calomel electrode in order to obtain good deposits. As in the determination of bismuth, finally the cathode potential was allowed to "rise" to  $-0.35$  volt. The results obtained were as follows:

TABLE XIII.

Cu + Sb + Bi present.	Cu + Sb + Bi found.	Error. %.	Cu + Sb + Bi. present.	Cu + Sb + Bi found.	Error. %.
0.7783	0.7787	+0.05	0.7805	0.7811	+0.09
0.7587	0.7589	+0.03	0.7338	0.7344	+0.09
0.7199	0.7189	-0.14	0.7754	0.7754	+0.00
0.5194	0.5188	-0.11	0.8077	0.8085	+0.10
0.6913	0.6916	+0.04			

From 45 to 60 minutes were required for the separation.

The bismuth was apparently deposited first, and at the same time the solution lost the blue-green color of the cupric ion; then a purple grape-colored alloy of copper and antimony began to be deposited, and the cathode potential fell, it being necessary to again raise the current; finally, a grayish black deposit of apparently pure antimony covered the electrode. Sometimes it happened that there were alternate depositions of the alloy and of the antimony, but the deposition of the alloy was heralded by a "drop" in the cathode potential.

**14. The Separation of Bismuth from Antimony.**—Definite quantities of bismuth oxychloride and of antimony oxide were weighed out into the same electrolyzing beaker, dissolved in 5–7 cc. of hydrochloric acid (sp. gr. 1.2), and the resulting solution was diluted up to 150 or 175 cc.; 4–8 g. of potassium tartrate were added, and the solution was boiled for several minutes. Two grams of hydroxylamine hydrochloride were added, the temperature was raised to 70°, and the solution was electrolyzed with the cathode potential limited to 0.20 volt against the normal calomel electrode. Since bismuth “burns” very easily while being deposited, it was necessary to watch the cathode potential carefully and to prevent it from exceeding the limit of —0.20 volt. The main electrolyzing current was reduced continuously until there was no further tendency for the cathode potential to rise. Long before this state of affairs was attained, the electrolyzing current was practically zero—yet it was necessary to continue electrolysis and to decrease the applied voltage until the cathode potential showed no disposition to rise. This required 20–30 minutes. By this procedure, bismuth was deposited quantitatively and entirely free from any antimony. The results obtained were as follows:

Sb <sub>2</sub> O <sub>3</sub> .	Bismuth.		Error. %.
	Present.	Found.	
0.20	0.3160	0.3150	—0.31
0.20	0.3288	0.3284	—0.12
0.30	0.3888	0.3888	±0.00
0.40	0.3451	0.3446	—0.20

The deposits were all in excellent condition.

**15. The Separation of Copper and Bismuth from Antimony.**—As the easiest method of removing a deposit containing antimony from the electrode is with nitric and tartaric acids, an attempt was first made to deposit copper and bismuth simultaneously from a nitric-tartaric acid electrolyte which contained these metals and antimony. A triple alloy obtained as stated in Section 13 was dissolved in the minimum amount of nitric acid and 5–6 g. of tartaric acid. The solution was diluted to 150 or 175 cc. and electrolyzed. The temperature was kept at 25° or below, as in the separation of copper from antimony in the same electrolyte (Section 11). At the beginning of the deposition, the cathode potential was about —0.10 volt against the normal calomel electrode, but toward the end it was allowed to rise to —0.20 volt. Copper was the first metal to be deposited; this order was the opposite of that observed in chloride electrolytes. The solution was not free of copper when the color of the cupric ion had disappeared, but a considerable amount of copper was still present in the cuprous state while bismuth was being deposited. It happened quite often that there were alternate depositions of bismuth and of copper long after all color had disappeared. On ac-

count of the solubility of the copper in the nitric acid, siphon washing was resorted to in most instances. Some of the results which we obtained are as follows:

TABLE XIV.

Sb present.	Cu + Bi present.	Cu + Bi found.	Error. %.
0.20	0.5368	0.5347	—0.40
0.40	0.4794	0.4814	+0.40
0.20	0.4607	0.4629	+0.45
0.30	0.5303	0.5298	—0.10
0.20	0.5005	0.5034	+0.58
0.20	0.4594	0.4608	+0.30

The end point of the determination was indistinct, and the high results show that, in the deposition of the last traces of copper, antimony in small amounts was probably deposited with it. The results were not considered satisfactory.

We next tried the separation in acidified chloride electrolytes. A triple alloy obtained as in Section 12 or 13 was dissolved from the platinum electrode as follows: 25–30 cc. of 1 : 3 hydrochloric acid were warmed up to about 60° in an electrolyzing beaker, the electrode was put in, and then a very few drops of conc. nitric acid were added, care being taken to use the least amount necessary to start a moderate attack on the alloy. When all of the sample had been dissolved, crushed ice was added sufficient to lower the temperature to 10° or below; then about 5 g. of tartaric acid were added. Electrolysis was carried out at this low temperature; at higher temperatures there appears to be an extensive formation of a complex tartrate-copper ion, from which the copper cannot be recovered. From time to time, small lumps of ice were added to the electrolyte to keep its temperature down.

The cathode potential was limited at the beginning to —0.15 or —0.20 volt against the normal calomel electrode, but to deposit the last of the copper it was allowed to rise to —0.40 volt. Hydrogen began to be evolved soon after, and the experiment was terminated. From 90 to 120 minutes was the time required for the deposition of the samples in the table below.

TABLE XV.

Sb present.	Copper and bismuth.		Error. %.
	Present.	Found.	
0.23	0.5552	0.5558	+0.10
0.30	0.6750	0.6748	—0.03
0.30	0.7156	0.7162	+0.08
0.20	0.6752	0.6746	—0.09

**16. The Separation of Bismuth from Copper.**—Bismuth cannot be separated from copper by the "graded potential" method, but either bismuth or copper can be separated from antimony. When all three metals

are present, the first procedure to suggest itself is to remove either bismuth or copper from the solution, and to separate the other two by one of the methods given above. Hence we made a complete study of Moser's method<sup>1</sup> for precipitating bismuth phosphate in order to ascertain if bismuth could thus be removed quantitatively from solutions of these three metals.

Pure deposits of bismuth were prepared according to the directions in Section 4. The deposit was dissolved in the least possible amount of nitric acid (3-5 cc.). Tartaric acid was also used in order to reproduce the conditions which would be obtained in an actual separation of bismuth from copper and antimony. A slight excess of a 10% solution of ammonium phosphate was added to the hot solution. After a short period of digestion, the precipitate was transferred to a filter paper, and was washed with a decinormal solution of nitric acid to which a few cubic centimeters of the precipitant had been added. The bismuth was dissolved in hydrochloric acid and deposited according to the method given above for its determination. This was done first, with bismuth alone in the solution, then with copper present, and finally in the presence of antimony. The following results were obtained:

TABLE XVI.

Cu.	Sb.	Tartaric acid.	Bismuth.		Error. %.
			Present.	Found.	
None	None	5 g.	0.9172	0.9140	-0.34
None	None	5 g.	0.6860	0.6859	-0.01
None	None	5 g.	0.8912	0.8912	±0.00
0.25	None	5 g.	0.5678	0.5666	-0.21
0.12	None	5 g.	0.6066	0.6042	-0.39
None	0.24	5 g.	0.6068	0.6233	+2.7
None	0.16	5 g.	0.6068	0.6200	+2.1

These results show that bismuth phosphate is precipitated quantitatively and in pure form when it is present alone in the electrolyte or together with copper, but not when it is together with antimony. On this account the order of procedure above suggested had to be changed to the following:

The copper and bismuth were separated from antimony by the method given in Section 15, and then the bismuth was separated from the copper by the method given above. The following results were obtained:

TABLE XVII.

Cu.	Bismuth.		Error. %.
	Present.	Found.	
0.26	0.5128	0.5118	-0.20
0.37	0.2589	0.2580	-0.40
0.25	0.2312	0.2318	+0.26

## THE ELECTROANALYSIS OF SILVER WITH SOLUTIONS OF SILVER CHLORIDE IN AMMONIA.

By E. P. SCHOCH AND F. M. CRAWFORD.

Received May 6, 1916.

A method for the quantitative electrodeposition of silver out of solutions of silver chloride in ammonia has not been published so far, but the use of this electrolyte appears to be very desirable, because it is likely to yield pure deposits while the cyanide electrolyte—the only other solvent for silver chloride heretofore employed in electroanalysis—produces impure deposits.

We have found that approximately 99.6% of the silver in an ammoniacal solution of silver chloride can be deposited by electrolysis in good form. It is merely necessary to increase the conductivity of the solution by adding enough of an ammonium salt (ammonium chloride) to the solution, and to electrolyze with a small current density at the ordinary temperature.

In order to deposit the small remnant of silver left in the electrolyte, the ammonia is neutralized with a slight excess of hydrochloric acid, and a weak reducing agent (oxalic acid) is added: from this electrolyte the remainder of the silver may be deposited completely and in good form. The presence of nitrates (or of nitric acid in the original mixture) does not affect the result.

Care must be taken to clean the platinum cathode thoroughly, to keep the current density small in order to avoid "burning" the deposit, and to wash and handle the electrode with the deposit *gently* to avoid knocking off the deposit. With a little care on these points, the determination is easily carried out and gives satisfactory results, as is shown below.

The following determinations were made with the electrolytic apparatus described in the foregoing paper by E. P. Schoch and D. J. Brown: Samples of pure sheet silver were dissolved in concentrated nitric acid and the silver was precipitated with a slight excess of hydrochloric acid. With several of the samples, the silver chloride was filtered, washed and dissolved in a slight excess of concentrated ammonia; and with others the original mixture (containing the excess of nitric acid) was treated with ammonia. About 20 g. of ammonium chloride and enough water were added to each mixture to bring the volume to approximately 150 cc. (enough to cover the electrodes), and the solutions were electrolyzed at room temperature with an initial amperage of 0.35 amp. (which with our apparatus required 1.1 volts between the electrodes). This voltage was kept constant until the current had dropped to zero: care had to be taken to reduce the current promptly while the metal was being deposited because the maximum allowable current density (which

cannot be exceeded without obtaining a dark and loosely adherent deposit) rapidly becomes less as the silver content of the solution becomes less. When the amperage had become practically zero, the voltage was allowed to rise gradually to 1.3-1.4 volts and electrolysis continued until a total of 25-30 minutes had elapsed. This period must necessarily be larger if the quantity of silver to be deposited is greater than that which we used.

Then, without disturbing the apparatus, about 3 g. of oxalic acid crystals were added to the solution, and enough concentrated hydrochloric acid to make the solution faintly acid to litmus paper. Without increasing the applied voltage, electrolysis was continued for about 20 minutes. Then the experiment was terminated, and the electrodes were washed and dried in the manner described in the preceding paper. The following results were obtained:

TABLE I.—DEPOSITION OF SILVER.

## TITRAMETRIC DETERMINATION OF NITRITES.

By B. S. DAVISSON.

Received May 10, 1916.

The frequent necessity of determining nitrites in the investigation of the physiology of the process of nitrification, reveals the need of a satisfactory titrametric method for such determination.

Nitrite determinations are usually made by colorimetric methods. It would be more desirous to make nitrite determinations titrametrically and avoid the errors which are so often introduced in colorimetric methods, namely, errors of dilution, eye fatigue, color comparison and the individual error of the worker.

### Historical.

The reaction of nitrous acid with hydriodic acid is well known:  $2\text{HI} + 2\text{HNO}_2 \rightarrow 2\text{H}_2\text{O} + 2\text{NO} + \text{I}_2$ . Since this reaction proceeds quantitatively, titration of the liberated iodine with standard thiosulfate has been used as a titrametric method for determining nitrous nitrogen. The

nitric oxide evolved in the reaction passes readily back into nitrous acid in contact with air and water and will oxidize more hydriodic acid, unless air is excluded from the titrating flask.

Winkler<sup>1</sup> has worked out a time method for determining small amounts, less than  $\frac{1}{3}$  mg., of nitrites in waters. The method depends upon the reactions taking place in the presence of oxygen. After the solution has stood for some time in contact with the acid, iodide and starch solution, the liberated iodine is titrated with 0.005 *N* sodium thiosulfate. The author compiled a table showing the milligrams of  $N_2O_3$  in a liter of the solution for a given quantity of the thiosulfate. The table is compiled for periods of 3, 6 and 24 hours. The author recommends the 24-hour period as giving the most satisfactory results.

Winkler<sup>2</sup> proposed a second method for determining nitrites when the quantity present is greater than  $\frac{1}{3}$  mg.  $N_2O_3$ . He used  $KHCO_3$  as a source of  $CO_2$  to expel the air from the titration flask. After ten minutes the iodine is titrated.

Sutton<sup>3</sup> outlines the Dustan and Dymond method in which the air is expelled from the flask by boiling the solution of acid, starch and potassium iodide and closing off the flask with a pinchcock, thus creating a vacuum when the solution cools. The nitrite solution is then introduced and the liberated iodine titrated with standard thiosulfate.

Wiley<sup>4</sup> outlines the Chabier method for the quantitative determination of nitrites. The air is expelled from the titrating flask by carbon dioxide or illuminating gas. The reaction of the acid, potassium iodide, and starch solution is allowed to take place after the air is expelled, and the liberated iodine is titrated with standard thiosulfate.

### Experimental.

The two methods proposed by Winkler were investigated. The procedure was the same as that employed by Winkler.

The results obtained by the first method were too high in practically all of the determinations made. No satisfactory results were obtained from a great number of trials.

Since this method depends upon the reaction taking place in the presence of oxygen, it seems probable that one might pass a slow current of air through the solution and accomplish the desired oxidation in a very short time. This, of course, would require the formulation of another table to be used in connection with the method.

Winkler's second method gave no better results than those obtained by his time method. Trouble was experienced in getting all the oxygen out

<sup>1</sup> *Z. Nahrungs und Genussmittel*, 29 (1915).

<sup>2</sup> *Loc. cit.*

<sup>3</sup> "Volumetric Analysis," 10th Ed., p. 287.

<sup>4</sup> "Princip. and Pract. of Agric. Analysis," 2nd Ed., Vol. II, p. 474.

of the flask. Five grams of  $\text{KHCO}_3$  as recommended by Winkler, was not sufficient. It is necessary that no air enter the flask during titration and this can be accomplished only when a rapid current of  $\text{CO}_2$  passes out of the solution. The results obtained with this method were in every case too high.

The work was carried no further on the method proposed by Winkler. The method cannot be used where large quantities of nitrites are present. Since the amount of nitrite which we wish to determine may be large or very small, it was thought better to develop a method which can be used with both large and small quantities of nitrites.

The Dustan and Dymond method was next used. Special burets were prepared for the standard thiosulfate and nitrite solutions. The burets were connected with the flask through a two-way stopcock and all air was excluded in making the connections. It was found almost impossible to prevent the leakage of air into the flasks. Air was drawn in about the rubber stoppers, though they appeared to be very tight. A method simpler in manipulation and still capable of a high degree of accuracy was sought.

Since the iodometric method of determining nitrite nitrogen depends upon the determinations being carried on in the absence of oxygen, it would be better to expel the air by means of some inactive gas and make the titrations while a slow current of this gas is passing through the flask. The Chabier method with some improvements should give trustworthy results for fractions of a milligram. The starch iodide reaction is extremely delicate and if careful precautions are taken to expel all air one should get excellent results.

Either natural gas or commercial carbon dioxide may be used to expel the air from the titration flask. These gases were each found to be effective. The low cost and ease of handling of carbon dioxide makes it easily available for this purpose and it is used in this laboratory. It requires no further purification and can be passed directly from the cylinder through the flask.

A special aeration flask was used, as shown in Fig. 1. It is a large-mouthed Erlenmeyer flask with an aerating tube sealed through the side and extending to the bottom of the flask where an arm is bent parallel to the flask bottom. The tube has several openings on either side to permit a rapid escape of gas. Such an arrangement gives good distribution of the gas and enables one to get immediate expulsion of the air. The flask is closed with a rubber stopper bearing an outlet for the gas, a separatory funnel for introducing the acid, a buret for the standard thiosulfate and a second

Fig. 1.

buret to carry a standard nitrite solution to be used in case the end point is overstepped. A stand with a white porcelain base is used with the apparatus.

**Procedure.**—Bring the solution to be tested into flask A and make to a volume of about 150 cc. Add 0.5 g. of pure KI and 2 cc. of a starch solution. Insert the stopper and allow a slow current of  $\text{CO}_2$  to pass through the flask for three minutes. Reduce the current of  $\text{CO}_2$  to a few bubbles, just sufficient to prevent any diffusion of air into the flask during titration. Add about 10 cc. of a 15% solution of  $\text{H}_2\text{SO}_4$ , and allow the solution to react for a short time before titrating the liberated iodine with thiosulfate.

The results reported in this paper were obtained upon a standard nitrite solution. The nitrite solution was prepared from silver nitrite, the silver being precipitated from the solution with sodium chloride. The solution was filtered, the precipitate washed free of nitrites and the solution then made to a definite volume. Standard thiosulfate of 0.1 N, 0.05 N, 0.02 N and 0.005 N strengths were used for making titrations.

Table I contains results obtained where variable quantities of a standard nitrite solution were used. Twentieth normal thiosulfate was used in making the titrations.

TABLE I.

Nitrite solution. Cc.	$\text{Na}_2\text{S}_2\text{O}_4$ . Cc.	Nitrogen taken. Mg.	Nitrogen found. Mg.	Error.
25.06	12.07	8.51	8.47	—0.04

7.....	10.74	15.03	7.26	2.03
Theoretical.....	...	15.10	..	2.01

The method should give accurate results in the presence of organic matter if it is to be used in the study of the physiology of nitrification.

The effect of organic matter was next studied. Determinations were made in the presence of soil extract which contained considerable organic matter. Fifty cc. of a standard nitrite solution were added to 50 cc. of a soil extract and the nitrite was determined. Nitrites were determined separately on 50-cc. portions of the soil extract and the proper correction, 0.448 mg., was made.

TABLE III.—EFFECT OF ORGANIC MATTER ON NITRITE DETERMINATION. AMOUNT TAKEN, 10 MG. OF NITROGEN.

Cc. 0.1 <i>N</i> <i>Na</i> <sub>2</sub> <i>S</i> <sub>2</sub> <i>O</i> <sub>3</sub> .	Nitrogen found. Mg.	Nitrogen recovered. Mg.	Cc. 0.1 <i>N</i> <i>Na</i> <sub>2</sub> <i>S</i> <sub>2</sub> <i>O</i> <sub>3</sub> .	Nitrogen found. Mg.	Nitrogen recovered. Mg.
7.46	10.45	10.00	7.46	10.45	10.00
7.47	10.46	10.02	7.50	10.50	10.05
7.48	10.47	10.03	7.50	10.50	10.05
7.48	10.47	10.03	7.47	10.46	10.00

The organic matter of the extract does not affect the results very materially. In extreme conditions, however, the nitrites may be removed from a second sample by boiling with acetic acid, and the magnitude of the action due to organic matter determined by means of a blank titration.

Small quantities of nitrites may be determined in the open flask while a current of CO<sub>2</sub> is passing through the solution. Table III contains the results of such determinations. For very small quantities of nitrites 0.005 *N* thiosulfate is used.

TABLE IV.—AMOUNT TAKEN, 0.012 MG. NITROGEN.

Cc. 0.005 <i>N</i> <i>Na</i> <sub>2</sub> <i>S</i> <sub>2</sub> <i>O</i> <sub>3</sub> .	Mg. nitrogen.	Cc. 0.005 <i>N</i> <i>Na</i> <sub>2</sub> <i>S</i> <sub>2</sub> <i>O</i> <sub>3</sub> .	Mg. nitrogen.
0.19	0.013	0.18	0.012
0.16	0.011	0.17	0.012
0.14	0.009	0.18	0.012
0.19	0.013	0.16	0.011
0.19	0.013		

The results reported in this paper show clearly that nitrous nitrogen can be determined titrimetrically when care is taken to expel the air from the titration flask with some gas which will not affect the determination.

The author takes this opportunity to thank Mr. J. J. Kennedy and Dr. E. R. Allen for their assistance in carrying on this work.

## SODIUM PYROGALLATE AS A REAGENT FOR THE DETERMINATION OF OXYGEN.

By J. W. SHIPLEY.

Received June 21, 1916.

TOPICAL OUTLINE.—Introduction and Historical. Reagents. Apparatus. Range of Concentrations. Specific Absorption of Reagents. Comparison with Potassium Pyrogallate. Volume of Oxygen Absorbed before Rate of Absorption Dropped to Four-minute Limit. Rate of Absorption. Temperature Coefficient. Relation of

Oxygen Absorbed to Amount of Pyrogallol. The Formation of Carbon Monoxide. Rate of Absorption in Various Pipets. Choice of Reagents for Gas Analysis. The Use of Ammonium and Barium Pyrogallate. Summary.

### Introduction and Historical.

The purpose of this research was to determine whether sodium pyrogallate might not be substituted for potassium pyrogallate in the absorption of oxygen from gaseous mixtures.

The evidence from the chemical literature available indicated that no one as yet had made a systematic study of the use of sodium pyrogallate in this connection and that chemists had on very doubtful evidence indeed discarded this reagent in favor of the more expensive potassium salt. Particularly at this time when circumstances have made it almost impossible to obtain the latter foreign product in any quantity did it seem desirable to determine whether the home product might not be as serviceable.

Potassium hydroxide is at present universally used in the preparation of alkaline pyrogallate for the absorption of oxygen. All text-books on gas analysis recommend its use and many researches have been carried out to determine the best proportion of alkali, pyrogallate and water to use in the preparation of the reagent. The best conditions for obtaining the most efficient absorption of oxygen by means of this reagent was the subject of a recent exhaustive research by R. P. Anderson.<sup>1</sup> Anderson made one determination with sodium pyrogallate in place of potassium pyrogallate, obtaining complete absorption only after twelve minutes' shaking. From this he concludes that such a reagent would scarcely be satisfactory for general use as an absorbent for oxygen.

Weyl and Goth<sup>2</sup> carried out a series of experiments, the results of which tended to indicate that sodium hydroxide might be better than potassium hydroxide in the preparation of this reagent.

Berthelot<sup>3</sup> found that the relative absorbing capacity of sodium and potassium pyrogallate was practically equivalent when the solution contained alkali in the proportion of three parts of alkali to one of pyrogallol. Dilution affected the rate of absorption and the evolution of carbon monoxide but the total absorbing power was not affected until the ratio between pyrogallol and alkali used dropped below 1 : 1. At 1-2 KOH to 1 of pyrogallol the amount of oxygen absorbed was reduced to one-half of that absorbed when the ratio was 3 : 1, respectively.

Lewes<sup>4</sup> prepared a reagent by dissolving 10 g. of pyrogallol in 150 cc. of 20% sodium hydroxide. Such a solution required twenty minutes for the complete absorption of oxygen and could not be used more than three

<sup>1</sup> Anderson, *J. Ind. Eng. Chem.*, 7, 587 (1915).

<sup>2</sup> Weyl and Goth, *Ber.*, 14, 2659 (1881).

<sup>3</sup> Berthelot, *Ann. Chem. et Phys.*, 77, 294 (1898).

<sup>4</sup> Lewes, *J. Soc. Chem. Ind.*, 10, 407 (1891).

or four times, since carbon monoxide was generated after a certain proportion of oxygen had been absorbed. Had Lewes gone further and used more concentrated solutions with respect to both alkali and pyrogallol he would have found the rate of absorption of oxygen much greater and would not have found any appreciable quantity of carbon monoxide.

The experimental work of Weyl and Goth at relatively low concentrations and of Berthelot at high concentrations indicated that sodium hydroxide might well have been considered in the preparation of alkaline pyrogallate. Chemists<sup>1</sup> have, however, in this as in many parallel cases, accepted the preference for a potassium compound without investigating fully the possible substitution of the cheaper sodium salt.

The results of a few preliminary determinations covering several different concentrations indicated clearly that the absorption of oxygen by sodium pyrogallate was sufficiently rapid to warrant a more extensive investigation. Moreover, no carbon monoxide appeared to be evolved from any of the concentrations used. Accordingly, apparatus and reagents were prepared for determining the best conditions and concentrations of sodium pyrogallate for the absorption of oxygen from gaseous mixtures.

**Reagents.**—Pyrogalllic acid was secured from the 1-pound can product prepared by a reputable firm.

Sodium hydroxide solution was prepared by dissolving electrolytic, pure stick sodium hydroxide in an equal weight of water. The alkali content of this solution was determined by diluting 10.0 cc. to a liter and titrating an aliquot portion against standard acid. Thus 10.0 cc. were found to contain 7.36 grams of sodium hydroxide or about 49.1%. This solution will be referred to as the stock solution.

Oxygen was prepared from the reaction between sodium peroxide and water. The preparation contained 95% of the gas.

**Apparatus.**—Fig. 1 illustrates in detail a special pipet outwardly resembling the Richard's form and inwardly that of the Orsat model.

Such a double pipet was found to be very efficient. It is com-

Fig. 1.

<sup>1</sup> Withrow, *J. Ind. Eng. Chem.*, 8, 486 (1916).

pact, stable, easy to construct or repair, not at all fragile and very convenient for filling or cleaning. The small glass tubes provide a very large absorbing surface and since no shaking is necessary the disadvantage arising from foaming when viscous solutions are used is entirely obviated.

This pipet was used in making the absorptions tabulated in Table I.

**A Simple Pipet.**—In determining the specific absorption of various alkaline pyrogallate solutions it was necessary to have a simple pipet and that depicted in Fig. 2 was found to give very satisfactory results. This pipet resembled in principle that described in Fig. 1.

A glass tube 6 mm. in diameter was sealed to the lower extremity and to this was attached a levelling bulb filled with mercury. A three-way capillary stopcock, C, Fig. 2, was sealed to the upper end of the pipet;

Fig. 2.

one arm led to the gas buret while to the other was sealed a 5 cc. pipet graduated in tenths. The gas buret was likewise provided with a three-way capillary stopcock, F, one arm being connected at K by pressure tubing with the corresponding arm of the absorption pipet, while the other, H, permitted the filling of the buret with air or with oxygen from the oxygen tank.

The carbon monoxide absorptions were made in the ordinary pipet of the Orsat apparatus.

**Range of Concentrations.**—A series of determinations was made for the purpose of finding out the range of concentration over which the rate of absorption was sufficiently rapid for the purpose in question. A weighed portion of pyrogalllic acid was placed directly into the pipet, Fig. 1, followed by a few cubic centimeters of water to prevent caking when the alkali solution was added. Depreciation of the reagent through contact with the air was obviated by filling the pipet with illuminating gas before adding the alkali.

The results collected in Table I represent the average of a number of determinations for each solution carried out by passing 50.0 cc. portions of air back and forth over the reagent three times in four minutes.

TABLE I.  
Time of Absorption of Oxygen by Sodium Pyrogallate.

**Specific Absorption of Reagents.**—Since complete and rapid absorption of the oxygen over a considerable range in concentration was secured, the determinations of the specific absorption of the reagent for various concentrations was next carried out. This was done in the pipet already described in Fig. 2. The reagent with predetermined proportions of alkali, acid, and water was always prepared in a small dropping funnel. The required weight of pyrogalllic acid together with from one to four cubic centimeters of water—to prevent caking—was placed in the funnel and the air swept out with illuminating gas, by connecting the funnel in series with a Bunsen burner. The lighted burner disposed of the excess gas. Ten cubic centimeters of alkali from the stock solution were

next run in from a pipet and the funnel stoppered. The stem of the funnel was also provided with a stopper to prevent the gas from being displaced by air. The mixing of the alkali and pyrogallol was always accompanied by a considerable rise in temperature, but this apparently had no deleterious effect upon the reagent.

After cooling, five cubic centimeters of the reagent were transferred to the graduated pipet of the absorption apparatus, care being exercised to prevent any contact whatsoever with the air. The absorptions were carried out with 1.5 cc. portions of the reagent measured into the pipet by means of the graduate. Oxygen in measured volumes was introduced through the gas buret and passed to and fro between the pipet and buret until the rate of absorption had dropped to one cubic centimeter per ten minutes. To have waited for complete exhaustion of the reagent would have made the determinations interminable, so this arbitrary ending of the reaction was chosen. For comparative purposes and for the purposes of this investigation the data so secured were quite sufficient. The time required for an absorption was about one and one-half hours. Between each determination the gas buret was detached from the pipet, the residual liquor run out through K, and the pipet cleaned and dried.

TABLE II.  
Volume of Oxygen Absorbed by Sodium Pyrogallate.

10.....	12.0	+4	10.0	7.36	12.00	11.62	265.2

The densities of reagents No. 1 and No. 9 were determined at 20°/4 in an Ostwald-Sprengel pycnometer. Knowing the composition by weight of these reagents the density formed a ready and accurate means of determining the concentration of the constituents in the 1.5 cc. volume used.

**Comparison with Potassium Pyrogallate.**—Comparative determinations were made in the same apparatus using potassium pyrogallate instead of the sodium salt. 10 cc. of a solution of potassium hydroxide, made by dissolving 73.4 g. of stick alkali in 73.4 cc. of water were added to 10 g. of pyrogallie acid. 1.5 cc. of this solution absorbed 223 cc. of oxygen before the rate of absorption dropped to 1 cc. in 10 minutes. This

is practically the same volume as that for sodium pyrogallate of the same concentration. But absorption of the oxygen from 50 cc. of air under conditions identical with those for sodium pyrogallate required from 6 to 10 minutes instead of from 2 to 4 minutes as with the sodium salt.

3.5 cc. of the reagent, as prepared above, were diluted with 1 cc. of water. 1.5 cc. of this solution absorbed 197 cc. of oxygen before the rate of absorption had dropped to 1 cc. in 10 minutes. Complete absorption in four minutes was also obtained, but this continued only until 60 cc. of oxygen had been absorbed.

The dropping off in the rate of absorption for solutions containing a high concentration of pyrogallol limits the use of potassium pyrogallate to solutions of relatively low specific absorption. Anderson found that the specific absorption with 15 g. of pyrogallol in 100 cc. of solution was almost equal to that with 20 g. per 100 cc. But with sodium pyrogallate there is no such dropping off in specific absorption, and reagents containing 50 g. of pyrogallol per 100 cc. of solution are perfectly practicable.

It was also considered desirable to determine in our apparatus the absorption of oxygen by the potassium pyrogallate reagent recommended by Anderson as being the best solution for use in the Hempel double pipet. 1.5 cc. of this reagent absorbed about 30 cc. of oxygen from the air before the absorption was incomplete in 4 minutes and about 70 cc. of 95% oxygen before the rate of absorption dropped to 1 cc. in ten minutes. In comparison, the sodium pyrogallate of reagent No. 9 absorbed 154 cc. of oxygen from the air before absorption was incomplete in four minutes, and 222.4 cc. before the rate fell below 1 cc. in ten minutes. The reagent proposed by us has, therefore, five times the specific absorption of that recommended by Anderson as being the best for potassium pyrogallate.

**Volume of Oxygen Absorbed before Rate of Absorption Dropped to Four-minute Limit.**—For practical purposes the value of a reagent for the absorption of a gas ceases when the rate of absorption has decreased below a certain value. In this work complete absorption of the oxygen from 50.0 cc. of air when absorbed in the simple pipet, Fig. 2, was chosen as the limit.

1.5 cubic centimeter portions of solution No. 9 were treated with successive 50.0 cc. volumes of air at 20°, the residual gas being run off after each absorption. This was continued until absorption failed to be complete in four minutes with two transfers of the gas back to the buret. The average of three closely agreeing results gave 180 cc. of oxygen absorbed. Three similar absorptions carried out by first absorbing 125 to 130 cc. of oxygen from the 95% sample and then completing the determinations with 50.0 cc. volumes of air gave 154, 155 and 154 cc. of oxygen absorbed before the rate dropped below the four-minute limit.

Similar determinations on 1.5 cc. portions of solution No. 1 gave an absorption of about 20 cc. before the four-minute limit was reached.

The difference in the specific absorptions as found above for the same solution depending on the percentage of oxygen used, is, according to Hempel and Anderson,<sup>1</sup> the result of the deleterious effect of high temperature. With 95% oxygen the rise of temperature in the reagent was very marked indeed.

**Rate of Absorption.**—Two series of measurements of the rate of absorption of oxygen by the proposed reagent were made. The first consisted in observing the volume of oxygen absorbed by 1.5 cc. of the reagent in four minutes from successive 50.0 cc. portions of air together with the time required for complete absorption. The results for solution No. 9 are included here but they are typical of all. Only the last six observations are given, since all before these were identical with the 1st and 2nd.

50.0 cc. portion of air.	Vol. ab- sorbed in 4 minutes. Cc.	Time for complete absorption of oxygen. Minutes.	50.0 cc. portion of air.	Vol. ab- sorbed in 4 minutes. Cc.	Time for complete absorption of oxygen. Minutes.
1st.....	10.4	4	4th.....	9.2	11
2nd.....	10.4	4	5th.....	7.6	18
3rd.....	10.0	6	6th.....	4.0	50

The time necessary for complete absorption increased very rapidly. This is of special significance to the gas analyst. As soon as the rate of absorption of alkaline pyrogallate begins to drop off the reagent should be replaced by fresh solution, thus obviating the danger from incomplete absorption in a reasonable interval of time.

The second series of observations was made on the falling off in the rate of absorption when complete exhaustion of the reagent was being approached. The results for three solutions are plotted in Fig. 3. The ordinates represent the volume of oxygen absorbed by 1.5 cc. of the reagent when a considerable excess of 95% gas was present, while the abscissae indicate the time intervals in minutes corresponding to the volume reading. These observations were taken with the special apparatus already described and were accompanied by frequent passing back and forth of the gas between the pipet and the buret. Curve A is for solution No. 8 and requires to have 90.0 cc. added to it, since observations were not taken until the curve began to leave the vertical. Similarly Curve B, representing solution No. 6, must have 20 cc. added to it, while Curve C is that for solution No. 2 and represents the total volume of oxygen absorbed. The curves end when the rate of absorption had dropped to that of 1 cc. in ten minutes. The vertical portion of the curves, representing 210 cc. for solution No. 7, 120 cc. for No. 6 and 50 cc. for No. 2, indicates the volume of oxygen that might be absorbed by 1.5 cc. of

<sup>1</sup> Anderson, *Loc. cit.*

the respective reagents before exhaustion made further use of the reagent in gas analysis doubtful. The three curves are practically parallel and have the general direction of curves representing a reaction following the law of mass action.

Fig. 3.

**Temperature Coefficient.**—A series of determinations was carried out to establish the relationship of temperature to the rate of absorption. The time required by solution No. 9 to completely absorb the oxygen from equal volumes of air at different temperatures was taken as the basis for comparison. The absorption pipet was surrounded by a bath kept at the desired temperature and 50.0 cc. portions of air were run in from the gas buret, the time for complete absorption being noted. The gas was run back and forth twice in each case, excepting at the higher temperatures where absorption was complete without doing so. At temperatures above 40.0° absorption was so rapid that the time measurements could not be made with any degree of accuracy. The series, however, follows in general the law of Ostwald that the speed of a reaction doubles for each 10° rise in temperature. It also disposes of the contention<sup>1</sup> that alkaline pyrogallate is very much less active at a temperature of 7° than at 15°.

**Relation of Oxygen Absorbed to Amount of Pyrogallol.**—Table II contains the results of determinations made with ten different proportions of acid, alkali and water, ranging in concentration from a reagent containing but 10 g. of pyrogallol in 110 cc. of solution to a reagent from which sodium pyrogallate separated on cooling. It will be observed that the absolute alkali content was not varied throughout the series, that the water content was changed twice while the pyrogallic acid content was increased for each determination. At high concentration it was found necessary to increase the water content in order to prevent the crystallization of sodium pyrogallate and the consequent clogging of the apparatus. The composition of solutions No. 1 and No. 9 in respect to pyrogallol alkali and water may easily be calculated from the weight of these constituents used and the determined densities. The density of any of the intermediate solutions of Table II lies between that of 1.490 for No. 1 and 1.405 for No. 9. A slight increase in volume occurs as the pyrogallic acid content of a water solution increases so that direct comparison between the 1.5 cc. portions of the reagents used and the volumes of oxygen absorbed does not give the exact relation existing between pyrogallic acid and oxygen absorbed. But the results given in Table II indicate clearly that the absorption capacity is roughly directly proportional to the pyrogallic acid content.

Another cause of irregularity in this proportion was occasioned by the variable conditions under which the absorption of oxygen took place. A rapid rise in temperature always occurred and this rise was more marked for the solutions containing the higher proportions of pyrogallol. Moreover, since the gas used contained only 95% oxygen the residual gas contained varying proportions of oxygen for each determination. The residual gas containing the least proportion of oxygen would reach the chosen limit of absorption first. Replacing the residual gas with 60 cc. of 95% oxygen gave an increased absorption of 10 cc. to reagent No. 9 before the limit was reached.

Solution No. 10 was very viscous and on standing sodium pyrogallate crystallized out. For this reason further experimentation was carried out with the less concentrated solution No. 9.

The volume of oxygen absorbed by each gram molecule of  $C_6H_6O_3$  present in reagents No. 1 and No. 9 was calculated from the known weight of alkali, acid and water taken and the determined densities. Calculations based on the results given in Table II gave an absorption of 63.1 g. of oxygen for each gram molecule of  $C_6H_6O_3$  present in reagent No. 9.

and 59.1 g. for reagent No. 1. The result for the former was based on the complete exhaustion of the reagent while for the latter only to when the rate of absorption had become 1 cc. in ten minutes. Berthelot<sup>1</sup> found that for complete absorption with the sodium pyrogallate and potassium pyrogallate reagents he used, 48.5 g. of oxygen were absorbed per gram molecule of  $C_6H_6O_3$ , or three atoms of oxygen per molecule of  $C_6H_6O_3$ . Our results are from 30% to 40% higher than this and apparently do not follow so simple a proportion. Calculating the intermediate reagents of Table II on the basis of a density of 1.49 or 1.41 (between which limits the densities of the solutions must lie) gave results in every case much higher than those of Berthelot. With ammonium pyrogallate Berthelot obtained 66.4 g. of oxygen absorbed per gram molecule of  $C_6H_6O_3$ . Considering the variety of the oxidation products formed it seems unlikely that a simple relationship would exist between the oxygen absorbed and the  $C_6H_6O_3$  present, but that this relation would be a function of several variables such as temperature, viscosity, nature of absorbing vessel, relative concentration of oxygen, acid and alkali, etc. This view is consonant with the experimental evidence,<sup>2</sup> for by changing the conditions of oxidation for the same reagent carbon monoxide may or may not be formed, indicating clearly a marked change in the nature of the oxidation products. Moreover, it has been frequently observed that the temperature at which absorption takes place and the percentage of oxygen in the gas reacting affects the amount of oxygen absorbed.

De Forcrand<sup>3</sup> was not able to prepare pure mono and disodium pyrogallate from the reaction between sodium hydroxide and pyrogallic acid in aqueous solution. He always obtained a product containing a considerable proportion of resinous matter, and this when the reaction was carried out in an atmosphere of hydrogen. Trisodium pyrogallate on the other hand separated pure. One might expect, therefore, that with an excess of alkali present the absorption of oxygen would be more uniform, but Berthelot found that so long as he did not reduce the molecular proportions of alkali and pyrogallol below that of 1 : 1 the amount of oxygen absorbed remained the same as when the proportion was 3 : 1.

**The Formation of Carbon Monoxide.**—Throughout the course of this research numerous determinations were made for the detection of carbon monoxide in the residual gas after complete exhaustion of the reagents. The excess oxygen from the residual gas was absorbed in an Orsat pipet containing sodium pyrogallate reagent No. 5, Table II. After the complete absorption of the oxygen as indicated by no further change in volume on remaining in contact with the reagent for some time the gas was passed

<sup>1</sup> Berthelot, *Loc. cit.*

<sup>2</sup> Clowes, *Loc. cit.* This paper, p. 1699.

<sup>3</sup> De Forcrand, *Compt. rend.*, 115, 46, 48 (1892).

into another Orsat pipet containing freshly prepared ammoniacal cuprous chloride. Two such pipets were prepared, but as carbon monoxide was only found in one instance the second pipet was quite superfluous. To remove ammonia the gas was finally passed into a pipet containing a dilute solution of sulfuric acid. In order to be sure that the cuprous chloride pipet was functioning properly, air containing carbon monoxide was passed through the system of pipets in the same order as was the residual gas. A decrease in volume corresponding to the known amount of carbon monoxide in the gaseous mixture occurred in the cuprous chloride pipets. This check was run twice during the course of the analyses and once at the close.

No measurable quantity of carbon monoxide was detected in any of the reagents included in Table II. Special attention was given the proposed reagent No. 9, exhaustion being brought about under the varying conditions likely to occur in the application of this reagent for use in gas analysis. Speedy exhaustion with 95% oxygen and consequent high temperature of reaction, slow successive additions of oxygen without rise of temperature and exhaustion by successive volumes of air, all alike gave no appreciable absorption in freshly prepared cuprous chloride solution. One sample of gas was kept in contact with the reagent for a week after exhaustion was about complete, but no carbon monoxide was evolved. The potassium pyrogallate reagent, as recommended by Anderson, also failed to evolve any appreciable quantity of this gas. Experiments were next carried out with the sodium hydroxide reagent of Lewes. No generation of carbon monoxide was obtained when successive volumes of air were employed, but when 95% oxygen was used over 3.0 cc. of carbon monoxide was formed. This is in agreement with Clowes, who found that no carbon monoxide was formed when the gas contained less than 28% oxygen, but above that percentage the quantity became appreciable and increased as the alkali content was diminished. Evidently the alkali content used in the series of Table II was sufficient to prevent the formation of this objectionable gas in appreciable amounts. The non-formation of carbon monoxide was indirectly corroborated for the above reagents by the complete absorption of the oxygen from the air. Many determinations on 50.0 cc. volumes of air were made when the rate of absorption was under investigation. If carbon monoxide had been evolved in appreciable amounts it would have been indicated as incomplete absorption. Such did not occur in any one of the reagents listed in Table II. The volume of oxygen absorbed always agreed with that corresponding to the percentage composition in the atmosphere.

Concerning the conditions favoring the formation of carbon monoxide it may be pointed out that solution No. 9 contains only 2.3 molecules

of sodium hydroxide per molecule of pyrogallol while 3 molecules would be necessary for complete neutralization. The absence of carbon monoxide does not, therefore, appear to be dependent upon having an excess of alkali present as Clowes<sup>1</sup> contends.

**Rate of Absorption in Various Pipets.**—It was deemed desirable to try the proposed reagent in several different pipets. The table below gives briefly the results of these determinations.

TABLE IV.

Time of complete absorption of oxygen from 100.0 cc. air.

Reagent.	Hempel pipet.	Richards pipet.	Orsat pipet.	New pipet.
No. 9.....	10-15 min.	10-15 min.	4-6 min.	4-6 min.
No. 5.....	.....	.....	4-6 min.	4-6 min.

Complete absorption was obtained with from three to four transfers for the Orsat and the New pipet while with the Richards and the Hempel pipets double as many transfers combined with continual shaking failed to obtain complete absorption in less than ten minutes. Rhodes<sup>2</sup> found that nine minutes accompanied by nine transfers back and forth were necessary to obtain complete absorption of the oxygen from 100.0 cc. sample of air using the Orsat pipet and potassium pyrogallate.

It is hard to understand why the Hempel pipet should be longer used for any but very special work. It is difficult to fill with any reagent and especially so if the reagent is somewhat viscous. The long bent capillary is a source of weakness in structure and of irregularity in use. The enormous friction of the liquid in the capillary requires, even with comparatively fluid reagents, a considerable excess of pressure to overcome and prohibits entirely the use of many concentrated reagents because of their viscosity. Moreover the pipet requires a special and expensive stand while shaking has to be resorted to in order to obtain efficient absorption. Should the pipet be broken anywhere only an experienced glass blower can repair it.

The Richards pipet is much simpler but is objectionable because of the necessity for shaking. Moreover having the bulbs above the stoppers with a comparatively long stem extending down to the bottom of the bottles gives an objectionable hydrostatic pressure when the apparatus is in use. The new pipet combines the good points of the Richards model with those of the Orsat type.

**Choice of Reagents for Gas Analysis.**—Table V gives the relative absorption capacity of 150 cc. of solutions No. 1 and No. 9 and the best KOH reagent as proposed by Anderson.

<sup>1</sup> Clowes, *J. Soc. Chem. Ind.*, 15, 170 (1896).

<sup>2</sup> Dennis, "Gas Analysis," p. 82.

TABLE V.

Volume of oxygen absorbed by 150 cc. of reagent before reaching four-minute limit.

Reagent.....	No. 1	No. 9	Best KOH reagent
Volume of oxygen absorbed, liters.....	2.2	15.3	3.0

Such a reagent as No. 9 is, therefore, five times as efficient an absorbing agent for oxygen as the best potassium pyrogallate solution.

Reagent No. 9 is somewhat viscous and in pipets provided with capillaries less than 1.5 mm. in internal bore, difficulty may be found in driving over the last portions of gas. With larger capillaries this reagent causes no difficulty whatsoever. Should a particular pipet have a small-bore capillary it would be advisable to use a more fluid reagent, such as No. 3 or No. 5.

Should difficulty in observing the position of the meniscus in the capillary be encountered because of the highly colored and viscous nature of the oxidation products, the running over of a very little water from the gas buret readily clears the tube for the final reading.

Such a reagent as No. 9 should replace in technical gas analysis the use of the more expensive and less efficient potassium solution. The saving of time and trouble in using a reagent lasting five times as long should alone decide in its favor. For use in a laboratory course in gas analysis, where only a comparatively small volume of oxygen is to be absorbed, reagent No. 3 would be found eminently satisfactory. Reagents No. 3 and No. 9 have been used in the laboratory classes of Ohio State and have proved quite satisfactory in every respect. No deterioration in the reagents was observed over a period of three months.

**The Use of Ammonium and Barium Pyrogallate.**—A reagent prepared by dissolving 10.0 g. of pyrogalllic acid in 10.0 cc. of 29% ammonium hydroxide precipitated on cooling a white crystalline substance soluble on heating but again separating on cooling. On adding 10.0 cc. more of the ammonium hydroxide the precipitate failed to dissolve. Evidently the trihydroxy benzene compound with ammonia is much less soluble than those of sodium hydroxide and potassium hydroxide. A second solution prepared by dissolving 10.0 g. of pyrogallol in 10.0 cc. of water and adding 160 cc. of 29% ammonium hydroxide gave complete absorption of the oxygen from 50.0 cc. of air in five minutes. Apparently, if occasion required, ammonium pyrogallate might be used for absorbing oxygen.

The insoluble barium compound of trihydroxy benzene made it impracticable for use in any but a very dilute solution. Moreover, the oxygen compound formed appeared to be insoluble and tended to clog the capillary connecting tube of the absorption apparatus while at the same time the rate of absorption was very low.

### Summary.

- (1) A new double pipet for liquid reagents in gas analysis is described.
- (2) The use of sodium pyrogallate as a reagent for the determination of oxygen in gases is proposed. Complete absorption in four minutes was secured from a number of solutions containing pyrogallol, sodium hydroxide and water in varying proportions. No carbon monoxide was detected in using the proposed reagent under varying conditions and the specific absorption of the best practicable solution was found to be five times that of the corresponding best solution for potassium pyrogallate.
- (3) The total volume of oxygen absorbed was found to be in excess of the proportion of 3 atoms of oxygen for each molecule of pyrogallol.
- (4) Ammonium and barium pyrogallate were found to be impracticable for general use in gas analysis.

## THE ESTIMATION OF THIOSULFATE SULFUR IN LIME-SULFUR SOLUTIONS BY IODINE TITRATION.

BY PHILIP L. BLUMENTHAL AND S. D. AVERITT.

Received May 10, 1916.

The question of the accuracy of the so-called "Iodine Methods" for the estimation of thiosulfates and polysulfids in commercial lime-sulfur solutions has vexed agricultural chemists for some years past. Recently one of us<sup>1</sup> published a paper in which he proved that the substance titrated with iodine after removing polysulfids, actually was thiosulfate, by means of a process in which tetrathionate was reconverted to thiosulfate and estimated.

Roark<sup>2</sup> stated that in the iodine titration there is reason to believe that iodine may cause an increased formation of sulfate, thus introducing an error.

We have undertaken to test the accuracy of the iodine method for thiosulfate in another fashion, namely, by converting the tetrathionate formed to sulfate and comparing this value with the titration figure.

### Experimental.

The following experiments were conducted with two objects in mind: to ascertain whether the oxidation of thiosulfate or tetrathionate to sulfate occurs sufficiently rapidly and in such quantity, particularly under poor working conditions, as to cause serious analytical errors; and to learn as much as possible about the chemistry of the lime-sulfur titration after the removal of polysulfid sulfur.

<sup>1</sup> S. D. Averitt, *J. Ind. Eng. Chem.*, **8**, 623 (1916).

<sup>2</sup> *J. Assoc. Off. Agr. Chem.*, **1**, 65.

Three portions of 0.05 *N* (factor 0.9948 0.05 *N*) thiosulfate were titrated exactly with approximately 0.1 *N* (factor 0.995 0.1 *N*) iodine solution to form tetrathionate, and a definite excess of iodine was added to each. The solutions were well stoppered and allowed to stand in the dark for two weeks. BaCl<sub>2</sub> was then added and the BaSO<sub>4</sub> weighed. Where the ratio of iodine to thiosulfate in two experiments was approximately 2 : 1, about 18% of the sulfur present was found as sulfate; with the ratio 3<sup>1</sup>/<sub>2</sub> to 1 in another experiment about 36% of the sulfur was found as sulfate. In each case, the blank for sulfate originally present in the thiosulfate was deducted. Evidently a considerable oxidation of *tetrathionate* occurred under the conditions of the experiment.

It is, therefore, conceivable that in a titration, if the iodine were to be run into a thiosulfate solution rapidly, without constant shaking, the formation of regional excesses of iodine might cause a slight oxidation of some of the tetrathionate first formed, to sulfate. In most cases this error would be small, since in a titration there is usually only a very short time in which iodine is in excess, and the action upon tetrathionate is by no means rapid.

To get an idea of the possible extent of this action, under working conditions, a series of experiments was conducted as follows:

Ten portions of 20 cc. each of a thiosulfate solution (0.1 *N*) were treated as follows: 1 and 2 had 2 cc. 10% BaCl<sub>2</sub> added and were then allowed to stand overnight, to permit the sulfates present to separate out. This served as a control on the sulfate content of the thiosulfate solution. 3 and 4 were carefully titrated with iodine solution, with constant shaking, so as to avoid regional excesses of iodine, and afterward the same amount of BaCl<sub>2</sub> was added. 5 and 6 were rapidly titrated, permitting regional excesses of iodine to form, shaking only toward the end of the titration so as to simulate careless work; after completion, BaCl<sub>2</sub> was added. 7 and 8 were similar to 3 and 4, except that BaCl<sub>2</sub> was added before titrating to remove SO<sub>4</sub> ions as rapidly as formed. 9 and 10 also had BaCl<sub>2</sub> added first and were otherwise identical with Nos. 5 and 6. To all except Nos. 1 and 2 a little 0.1 *N* HCl was added after the titration to prevent BaS<sub>4</sub>O<sub>6</sub> formed from decomposing, experience having shown that HCl stabilizes the barium salt. The average weight of BaSO<sub>4</sub> obtained in each pair was as follows: 0.55, 0.90, 0.95, 1.25 and 1.25 mg., respectively. The quantity of sulfate produced in the last four sets (3-10 inclusive) by the action of iodine upon tetrathionate was, therefore, 0.35, 0.4, 0.7 and 0.7 mg., respectively. A slight difference in the iodine titration values could be noticed. The averages of the titrations were 19.82 cc., 19.85 cc., 19.84 cc. and 19.86 cc., respectively, the maximum difference being 0.04 cc. in Nos. 9 and 10 as compared to Nos. 3 and 4. The differ-

ence in weight of  $\text{BaSO}_4$  between the averages of the same two sets is 0.35 mg. It would require 0.048 cc. of 0.1 *N* I to produce this amount of  $\text{BaSO}_4$  according to the equation  $\text{Na}_2\text{S}_4\text{O}_6 + 7\text{I}_2 + 10\text{H}_2\text{O} = 2\text{NaHSO}_4 + 2\text{H}_2\text{SO}_4 + 14\text{HI}$ , a good agreement considering the difficulty of estimating such small quantities. However, even if iodine does oxidize thiosulfate or tetrathionate all the way to sulfate, the quantity so produced in a lime-sulfur analysis would be almost negligible (less than 0.01% S), since the quantity of thiosulfate here employed is four to eight times as great as one encounters in actual analysis, according to the official procedure. It seems probable that in every titration a small quantity of iodine is used to produce sulfates by direct oxidation; we know of no method to prove this directly, since the error of weighing thiosulfate as  $\text{BaSO}_4$  is fully as great as the titration error, and there is no other method<sup>1</sup> known to us of standardizing a thiosulfate solution except by iodine titration of one kind or another.

In order to throw further light upon this sulfate-forming reaction and also upon the iodine titration methods as applied to lime-sulfur solutions, some experiments were carried out upon three lime-sulfur solutions which had already been analyzed by one of us (Averitt) during the progress of the work. Nos. 1 and 3 were commercial concentrates, No. 2 was made in the laboratory from pure chemicals and had a high thiosulfate content.

Three aliquots of Sample No. 1 were titrated with HCl to incipient acidity to methyl orange, the hydrogen sulfid was boiled out and  $\text{BaCl}_2$  added. The precipitated sulfur (and barium sulfate, if present) was filtered on fine-mat Gooch crucibles, dried, ignited and weighed. No barium sulfate was found, indicating absence of sulfate in the sample and reagents and that no sulfate was formed during the removal of  $\text{H}_2\text{S}$ . Similar results were obtained upon samples Nos. 2 and 3.

A second set of three aliquots each of Nos. 1 and 2 was treated as before with HCl and boiled and, after  $\text{BaCl}_2$  and starch had been added, the solution (containing precipitated sulfur) was titrated with approximately 0.1 *N* iodine solution. The iodine consumed represents thiosulfates and sulfites, if the latter are present—a disputed point. After standing overnight, a small amount of  $\text{BaSO}_4$  was found which, on each series of aliquots, averaged 0.7 mg. and 1.2 mg. of  $\text{BaSO}_4$ , respectively. This sulfate must have resulted either from the oxidation of sulfite or from the interaction of thiosulfate or tetrathionate with iodine.

Ashless paper filters were substituted for the Gooch crucibles after this, as it was found difficult to retain very small quantities of sulfate on asbestos.

<sup>1</sup> We have since heard of another method of standardization and hope to test it at a later period.

Three portions of 0.05 *N* (factor 0.9948 0.05 *N*) thiosulfate were titrated exactly with approximately 0.1 *N* (factor 0.995 0.1 *N*) iodine solution to form tetrathionate, and a definite excess of iodine was added to each. The solutions were well stoppered and allowed to stand in the dark for two weeks. BaCl<sub>2</sub> was then added and the BaSO<sub>4</sub> weighed. Where the ratio of iodine to thiosulfate in two experiments was approximately 2 : 1, about 18% of the sulfur present was found as sulfate; with the ratio 3<sup>1</sup>/<sub>3</sub> to 1 in another experiment about 36% of the sulfur was found as sulfate. In each case, the blank for sulfate originally present in the thiosulfate was deducted. Evidently a considerable oxidation of *tetrathionate* occurred under the conditions of the experiment.

It is, therefore, conceivable that in a titration, if the iodine were to be run into a thiosulfate solution rapidly, without constant shaking, the formation of regional excesses of iodine might cause a slight oxidation of some of the tetrathionate first formed, to sulfate. In most cases this error would be small, since in a titration there is usually only a very short time in which iodine is in excess, and the action upon tetrathionate is by no means rapid.

To get an idea of the possible extent of this action, under working conditions, a series of experiments was conducted as follows:

Ten portions of 20 cc. each of a thiosulfate solution (0.1 *N*) were treated as follows: 1 and 2 had 2 cc. 10% BaCl<sub>2</sub> added and were then allowed to stand overnight, to permit the sulfates present to separate out. This served as a control on the sulfate content of the thiosulfate solution. 3 and 4 were carefully titrated with iodine solution, with constant shaking, so as to avoid regional excesses of iodine, and afterward the same amount of BaCl<sub>2</sub> was added. 5 and 6 were rapidly titrated, permitting regional excesses of iodine to form, shaking only toward the end of the titration so as to simulate careless work; after completion, BaCl<sub>2</sub> was added. 7 and 8 were similar to 3 and 4, except that BaCl<sub>2</sub> was added before titrating to remove SO<sub>4</sub> ions as rapidly as formed. 9 and 10 also had BaCl<sub>2</sub> added first and were otherwise identical with Nos. 5 and 6. To all except Nos. 1 and 2 a little 0.1 *N* HCl was added after the titration to prevent BaS<sub>4</sub>O<sub>6</sub> formed from decomposing, experience having shown that HCl stabilizes the barium salt. The average weight of BaSO<sub>4</sub> obtained in each pair was as follows: 0.55, 0.90, 0.95, 1.25 and 1.25 mg., respectively. The quantity of sulfate produced in the last four sets (3-10 inclusive) by the action of iodine upon tetrathionate was, therefore, 0.35, 0.4, 0.7 and 0.7 mg., respectively. A slight difference in the iodine titration values could be noticed. The averages of the titrations were 19.82 cc., 19.85 cc., 19.84 cc. and 19.86 cc., respectively, the maximum difference being 0.04 cc. in Nos. 9 and 10 as compared to Nos. 3 and 4. The differ-

ence in weight of  $\text{BaSO}_4$  between the averages of the same two sets is 0.35 mg. It would require 0.048 cc. of 0.1 *N* I to produce this amount of  $\text{BaSO}_4$  according to the equation  $\text{Na}_2\text{S}_4\text{O}_6 + 7\text{I}_2 + 10\text{H}_2\text{O} = 2\text{NaHSO}_4 + 2\text{H}_2\text{SO}_4 + 14\text{HI}$ , a good agreement considering the difficulty of estimating such small quantities. However, even if iodine does oxidize thiosulfate or tetrathionate all the way to sulfate, the quantity so produced in a lime-sulfur analysis would be almost negligible (less than 0.01% S), since the quantity of thiosulfate here employed is four to eight times as great as one encounters in actual analysis, according to the official procedure. It seems probable that in every titration a small quantity of iodine is used to produce sulfates by direct oxidation; we know of no method to prove this directly, since the error of weighing thiosulfate as  $\text{BaSO}_4$  is fully as great as the titration error, and there is no other method<sup>1</sup> known to us of standardizing a thiosulfate solution except by iodine titration of one kind or another.

In order to throw further light upon this sulfate-forming reaction and also upon the iodine titration methods as applied to lime-sulfur solutions, some experiments were carried out upon three lime-sulfur solutions which had already been analyzed by one of us (Averitt) during the progress of the work. Nos. 1 and 3 were commercial concentrates, No. 2 was made in the laboratory from pure chemicals and had a high thiosulfate content.

Three aliquots of Sample No. 1 were titrated with HCl to incipient acidity to methyl orange, the hydrogen sulfid was boiled out and  $\text{BaCl}_2$  added. The precipitated sulfur (and barium sulfate, if present) was filtered on fine-mat Gooch crucibles, dried, ignited and weighed. No barium sulfate was found, indicating absence of sulfate in the sample and reagents and that no sulfate was formed during the removal of  $\text{H}_2\text{S}$ . Similar results were obtained upon samples Nos. 2 and 3.

A second set of three aliquots each of Nos. 1 and 2 was treated as before with HCl and boiled and, after  $\text{BaCl}_2$  and starch had been added, the solution (containing precipitated sulfur) was titrated with approximately 0.1 *N* iodine solution. The iodine consumed represents thiosulfates and sulfites, if the latter are present—a disputed point. After standing overnight, a small amount of  $\text{BaSO}_4$  was found which, on each series of aliquots, averaged 0.7 mg. and 1.2 mg. of  $\text{BaSO}_4$ , respectively. This sulfate must have resulted either from the oxidation of sulfite or from the interaction of thiosulfate or tetrathionate with iodine.

Ashless paper filters were substituted for the Gooch crucibles after this, as it was found difficult to retain very small quantities of sulfate on asbestos.

<sup>1</sup> We have since heard of another method of standardization and hope to test it at a later period.

Next, three portions, each containing 1 gram of concentrate (No. 3) were treated as follows: One portion, after being titrated with HCl, having BaCl<sub>2</sub> added and H<sub>2</sub>S boiled out, was titrated with iodine and allowed to stand several hours. The BaSO<sub>4</sub> weighed 1.0 mg. The filtrate was then oxidized with bromine and the barium sulfate weighed. Calculated from this figure, the thiosulfate sulfur was 0.51%, which was exactly the same as the iodine titration value.

The other two portions were titrated with HCl as before and the H<sub>2</sub>S was boiled out. After filtering out the precipitated sulfur, barium chlorid was added and the solution allowed to stand overnight. No precipitate was found, which proved the absence of sulfate in the original sample and also that none was formed during the removal of H<sub>2</sub>S by boiling from a barely acid solution. The samples were then titrated with iodine and allowed to stand overnight before filtering. The barium sulfate found weighed 1.2 and 1.1 mg., respectively. This sulfate came either from the presence of a small amount of sulfite or from the action of iodine on the tetrathionate or thiosulfate. The barium sulfate weighed from the oxidation of tetrathionate by bromine showed 0.51 and 0.54% sulfur as compared to 0.52 and 0.54% by the iodine titration.

### Conclusions.

The following points are considered as being established:

1. An excess of iodine does react with tetrathionate in neutral or faintly acid solutions, upon standing.
2. In every iodine titration on a lime-sulfur solution a small quantity of sulfate is formed; in some lime-sulfur solutions this is the only sulfate found.
3. The quantity of iodine used to form sulfate in an ordinary titration does not cause an appreciable error in the determination of thiosulfate.
4. The iodine values obtained after decomposing polysulfids by HCl titration actually represent thiosulfate, since the barium sulfate obtained from such solutions after oxidation agrees very closely with the titration values. The presence of sulfites, which would also be titrated at this point, would tend to cause high results for thiosulfate as calculated from the iodine value. If anything, the gravimetric results for thiosulfate are a trifle higher than the titration values, which points to an absence of sulfites, although this in itself is not absolute proof of the fact.

The authors are now investigating the velocity of the reaction between iodine and sodium tetrathionate in neutral and acid solution, and will present these results shortly. They desire to extend their sincere thanks to Dr. A. M. Peter, of this laboratory, for kind and helpful suggestions, during the progress of this work.

## DETECTION OF NICKEL IN COBALT SALTS.

BY A. R. MIDDLETON AND H. L. MILLER.

Received June 27, 1916.

The use of dimethylglyoxime as a reagent for the detection and determination of nickel, discovered by Tschugaev<sup>1</sup> in 1905 and developed by Brunk,<sup>2</sup> has become quite general. In addition to its simplicity of manipulation and freedom from interference by other metallic ions this reagent is unusually delicate. The brilliant scarlet color and extreme insolubility of nickel glyoximine<sup>3</sup> permits detection of one part of nickel in at least 350,000 parts of water and a modified method of using the reagent will be described in this paper by which we have been able to detect one part of nickel in more than 4,000,000 parts of water.

For the detection of traces of nickel in cobalt salts this reagent has not proved entirely satisfactory.<sup>4</sup> Cobalt combines with dimethylglyoxime to form an extremely soluble compound of brown color. Either because the nickel salt is soluble in this compound or, more probably, because the cobalt appropriates most of the reagent, no nickel is precipitated by ordinary amounts of reagent from cobalt salt solutions even though a considerable amount is present. The object of this investigation was to devise a method by which the cobalt ion should be suppressed, thus permitting the reagent to react with nickel only and avoiding the necessity for large amounts of reagent. Treadwell,<sup>5</sup> following a suggestion of Tschugaev, accomplishes this result by transforming the cobalt salt into a cobaltic ammine by concentrated ammonia and hydrogen peroxide before adding dimethylglyoxime. We shall show that this method is unsatisfactory and fails when much cobalt is present.

The most striking differences in the chemical behavior of nickel and cobalt are (1) the greater susceptibility of the latter to oxidation to the trivalent condition, and (2) the greater stability of its complex ions, both positive and negative. Of the various complex ions formed by cobalt the most stable are the complex cyanides, that of trivalent cobalt being decidedly more stable than that of bivalent cobalt. Nickel forms complex cyanides of a different type, resembling those of bivalent copper, whereas the cobalt cyanides are analogous to the iron cyanides. In the classic method of Liebig<sup>6</sup> for detecting nickel in cobalt salts, the inferior stability of the nickelocyanide ion together with the ready oxidizability of cobaltocyanide to cobalticyanide has long been used to effect a separation. a solution containing cobalticyanide, nickelocyanide and cyanide ions the following equilibria are involved:

The values of the instability constants are not accurately known, but it is certain that that of the cobalticyanide ion is extremely small and that of the nickelocyanide ion much larger. Any reduction of the concentration of the cyanide ion in the solution must result in decomposition of the nickelocyanide ion and considerable increase of nickel ion concentration while the much more stable cobalticyanide ion is less affected. In Liebig's method as modified by Gauhe<sup>1</sup> the cyanide ion is removed by oxidation with alkaline hypochlorite or hypobromite, the nickelous ion being simultaneously oxidized and precipitated as nickelic hydroxide. This method is not altogether satisfactory because cobaltic hydroxide is usually precipitated also and the appearance of a brown precipitate is by no means certain proof of the presence of nickel.

Since nickel glyoximine is decomposed by the cyanide ion, our problem was to remove the cyanide ion so gradually that the cobalticyanide ion should remain practically unaffected. For this purpose we have made use of the great stability of complex silver cyanide ions, together with the small solubility of silver argenticyanide,  $\text{Ag}[\text{Ag}(\text{CN})_2]$ , 0.0004 g. per liter at 20°.<sup>2</sup> For argenticyanide ion,  $[\text{Ag}'] \times [\text{CN}']^2 = 10^{-21} \times [\text{Ag}(\text{CN})_2']$ .<sup>3</sup> The comparative insolubility of silver cobalticyanide, accurate data for which are lacking, should also tend to prevent decomposition of the cobalticyanide ion. If to a solution containing alkali salts of nickelocyanide, cobalticyanide and a small excess only of cyanide, dimethylglyoxime be added and then dilute silver nitrate solution gradually, precipitation of silver argenticyanide removes the cyanide ion and promotes decomposition of the nickelocyanide ion, increasing the concentration of the nickelous ion, while the cobalticyanide ion is precipitated as  $\text{Ag}_3\text{Co}(\text{CN})_6$ , or, if not precipitated, is but slightly decomposed. Comparatively little dimethylglyoxime should then be sufficient to precipitate the small amount of nickel present, in part at least. The experiments recorded below show that this modification yields very satisfactory results.

### Experimental.

**Solutions and Reagents.**—Nickel sulfate solution from Kahlbaum's "Kobalt-frei" salt was standardized by electrolysis (0.05008 *N* and by precipitation and weighing as glyoximine 0.04968 *M*). Cobalt, if present, was in very small amount; we were unable to detect it with absolute certainty. Iron was found present and the discrepancy in the electrolytic

<sup>1</sup> *Z. analyt. Chem.*, **5**, 75 (1866).

<sup>2</sup> Bredig, *Z. physik. Chem.*, **46**, 602 (1903).

<sup>3</sup> Bodländer, *Z. anorg. Chem.*, **39**, 227 (1904).

and precipitation values is probably due almost entirely to its presence. Its removal appeared unnecessary for our purpose. The more dilute solutions used in the work were prepared from this solution by accurate dilution.

Cobalt sulfate solution, approximately 0.1 *M*, was prepared by working up residues from cobalt ammine salts. Nickel was removed by dimethylglyoxime according to the method we have developed and the solution as used gave no test for nickel. By electrolysis this solution was found to be 0.0921 *M*.

The other reagents used were: potassium cyanide, 10% solution; dimethylglyoxime, 1% solution in alcohol; and silver nitrate 1% solution.

**Sensitiveness of Dimethylglyoxime as Reagent for Nickel in Absence and in Presence of Silver Cyanide.**—Two 10 cc. portions of each of the  $\text{NiSO}_4$  solutions of the concentrations stated in Table I were taken. One was warmed to about 80°, 1 cc. of the dimethylglyoxime reagent added and a drop or two of dilute ammonia. The other portion was converted into the complex cyanide by adding two or three drops of KCN. At these small concentrations no precipitate of nickel cyanide was formed. The solution was warmed to 80°, 1 cc. of dimethylglyoxime reagent added, and then  $\text{AgNO}_3$  solution dropwise until a permanent white or pink precipitate formed. The more concentrated solutions thus treated gave at once pink precipitates; the more dilute ones white precipitates which turned pink on standing. In those solutions which required more than one hour to form a precipitate the exact time required for the pink color to appear was not recorded. In these cases the samples were observed after standing 24 hours. In the extreme dilutions of the simple ion the precipitate was frequently a single red crystal, very minute and difficult to see.

TABLE I.

0.000003	No ppt.	No pink color	0.000176	$1:5.3 \times 10^6$
0.000002	No ppt.	No pink color	0.000117	

From the results tabulated above it appears that the proposed modification shortens considerably the time required for the precipitate of nickel glyoximine to become visible and also makes possible the detection of somewhat smaller concentrations of the nickel ion. Apparently this

is due to increased concentration of these ions by adsorption upon the precipitated silver cyanide. As evidence in favor of this view it may be noted that we found that precipitation of silver chloride in extremely dilute solutions of the nickel ion and dimethylglyoxime was equally effective in hastening formation of the pink nickel glyoximine, while precipitation of a positive colloid, such as aluminium hydroxide, had no effect whatever. Since both silver cyanide and silver cobalticyanide are white, the red nickel glyoximine is readily seen as a pink tint in the white precipitate and the delicacy of the reagent is increased.

**Oxidation of Cobaltocyanide to Cobalticyanide.**—When KCN is added to a solution of a cobalt salt, brownish white  $\text{Co(CN)}_2$  is precipitated and then redissolved to a greenish brown solution of  $\text{K}_4\text{Co(CN)}_6$ . When warmed this changes soon to a pale yellow color and the color change is frequently assumed in manuals of analysis to indicate completion of oxidation. When  $\text{AgNO}_3$  was added soon after the color change took place, we found that the solutions darkened and dark gray precipitates were formed, while solutions which had stood for several hours after cyanide was added did not darken and gave pure white precipitates. When one of the darkened solutions became distinctly opalescent, we inferred that some silver ion had been reduced by cobaltocyanide which was still present, according to the reaction

By adding silver nitrate solution to freshly prepared solutions of cobaltocyanide we found that this reaction takes place very slowly in cold but rapidly in hot solutions. When the silver nitrate was added dropwise the hot solutions first became lighter in color, then gradually turned orange and darkened until a gray precipitate was formed. If the addition of silver nitrate was stopped when the orange tint appeared, no precipitate formed, but the solution darkened on standing and became opalescent due to the formation of colloidal silver. This reaction was found to be regularly reproducible in solutions of cobaltocyanide not less than 0.005 *M*.

We next investigated the time required after the color change to complete the oxidation, taking the failure to form metallic silver as evidence that oxidation was essentially complete. Ten cc. portions of 0.1 *M*  $\text{CoSO}_4$  were treated in casseroles with just enough KCN to dissolve the precipitates, heated nearly to boiling and continuously rotated in the casseroles for a definite time to hasten oxidation. The solutions were diluted to 100 cc. with water at 85° and silver nitrate was added dropwise with vigorous stirring. All solutions which had been warmed less than five minutes gave colloidal silver or dark precipitates; those heated for at least this period did not darken and gave pure white precipitates. Presumably the time required increases with the amount of cobalt. Gauhe<sup>1</sup> showed

<sup>1</sup> *Loc. cit.*

that the oxidation of cobaltocyanide requires considerable time, but his experiments appear to have been forgotten.

**Detection of Nickel in Cobalt Salts.**—We next determined the minimum amount of nickel that could be detected in varying amounts of cobalt salts by our silver method and, for comparison, by two of the older methods, Treadwell's and that of Liebig-Gauhe.

*A. The Silver Method.*—Definite volumes of solutions of  $\text{NiSO}_4$  and  $\text{CoSO}_4$  of known concentration were measured from burets into a casserole, KCN was added until the precipitate just dissolved and the solution heated and rotated for five minutes after the change of color was noted. The solution was then diluted with water at  $85^\circ$  to 50 cc., 1 cc. of dimethylglyoxime solution was added, and then silver nitrate dropwise with constant stirring until a permanent precipitate was produced. The time required for the pink color of nickel glyoximine to appear was observed. In cases where the time exceeded one hour, observations were made at the end of twenty-four hours. The results appear in Table II.

TABLE II.

In each expt. 10 cc.  $\text{CoSO}_4$  0.0921 *M*, equivalent to 54.31 mg. Co was used.

$\text{NiSO}_4$ .		Ni mg.	Ratio Ni : Co.	Ratio Ni : $\text{H}_2\text{O}$ . Approx.	Results.
Vol. Cc.	Molar conc.				
2.0	0.0005	0.0587	1:925	$1:0.85 \times 10^6$	Ppt. pink immediate
1.5	0.0005	0.0440	1:1234	$1:1.14 \times 10^6$	Ppt. pink 4 min.
1.0	0.0005	0.0293	1:1851	$1:1.71 \times 10^6$	Ppt. pink 6 min.
4.5	0.0001	0.0264	1:2054	$1:1.89 \times 10^6$	Ppt. pink 10 min.
4.0	0.0001	0.0235	1:2314	.....	Ppt. pink 20 min.
3.5	0.0001	0.0205	1:2644	$1:2.44 \times 10^6$	Ppt. pink 30 min.
3.0	0.0001	0.0176	1:3085	.....	Ppt. pink 24 hrs.
2.5	0.0001	0.0137	1:3702	$1:3.65 \times 10^6$	Ppt. pink 24 hrs.

Taking the minimum amount of nickel, 0.0205 mg., which could be detected in cobalt within thirty minutes, we studied the effect of larger proportions of cobalt. The procedure and final total volumes were the same as in the preceding experiments. The results are shown in Table III. and indicate that the sensitiveness of the test is not appreciably impaired by the presence of large amounts of cobalt.

TABLE III.

$\text{CoSO}_4$ 0.0921 <i>M</i> . Cc.	Mg. [Co.	Ratio Ni : Co.	Results.
15	81.47	1:3966	Ppt. pink 30 min.
20	108.62	1:5288	Ppt. pink 30 min.
25	135.78	1:6610	Ppt. pink 30 min.
30	162.93	1:7932	Ppt. pink 30 min.

*B. The Treadwell Method.*—10 cc. portions of 0.0921 *M*  $\text{CoSO}_4$ , equivalent to 54.31 mg. Co, with varying small amounts of  $\text{NiSO}_4$  were warmed with concentrated ammonia until a clear solution was obtained, hydrogen peroxide was added, and the solutions were heated till excess of peroxide

and ammonia was removed, diluted to 50 cc., 1 cc. of dimethylglyoxime solution was added and the time required for the precipitate of nickel glyoximine to appear was observed. The results are given in Table IV.

TABLE IV.

NiSO <sub>4</sub> .					
Vol. Cc.	Conc. molar.	Mg. Ni.	Ratio Ni : Co.	Results.	
10	0.0005	0.293	1:185	Red ppt.	1 hr.
9	0.0005	0.264	1:206	Red ppt.	1 hr.
8	0.0005	0.235	1:231	Red ppt.	1 hr.
7	0.0005	0.205	1:264	Red ppt.	24 hrs.
5	0.0005	0.147	1:370	Red ppt.	24 hrs.
4	0.0005	0.117	1:462	Red ppt.	24 hrs.

Taking the minimum amount of nickel that could be detected in one hour, 0.235 mg., the effect of larger proportions of cobalt was studied. The procedure and final volume of solution were the same as in the experiments recorded in Table IV. The results are shown in Table V. Apparently this method is not very sensitive and fails when much cobalt is present, at least with the small amount of dimethylglyoxime which was used.

TABLE V.

Cc. CoSO <sub>4</sub> , 0.0921 M.	Mg. Co.	Ratio Ni : Co.	Results.
10	54.31	1:231	Red ppt. after 1 hr.
15	81.47	1:346	No ppt. after 1 hr.
20	108.62	1:462	No ppt. after 1 hr.

*C. The Liebig-Gauhe Method.*—10 cc. portions of CoSO<sub>4</sub>, 0.0921 M, with varying amounts of NiSO<sub>4</sub> were treated with a slight excess of KCN over that required to dissolve the precipitate, and heated and rotated until complete oxidation of the cobaltocyanide had taken place. They were then diluted to 50 cc. and freshly prepared sodium hypobromite solution was added. After the precipitate had flocculated, it was filtered off, washed, dissolved in dilute HCl, neutralized with ammonia and tested for Ni with dimethylglyoxime.

TABLE VI.

NiSO <sub>4</sub> , 0.0005 M.	Cc.	Mg. Ni.	Ratio Ni : Co.	Results.
	9	0.2641	1:206	Blk. ppt. Ni confirmed
	6	0.176	1:309	Blk. ppt. Ni confirmed
	3	0.088	1:617	Blk. ppt. Ni confirmed
	2	0.059	1:925	Blk. ppt. No Ni
	1	0.029	1:1850	Blk. ppt. No Ni
None	None			Blk. ppt. No Ni

This method appears able to detect 0.1 mg. nickel in a volume of 50 cc., but a confirmatory test must in every case be applied as the precipitate always contains cobaltic hydroxide if the hypobromite is added to a warm solution. Even if the temperature is kept low, Co(OH)<sub>3</sub> frequently precipitates.

Comparing the results of the three methods, the minimum amount of nickel detectable within one hour in a volume of 50 cc. is found to be:

Silver method.....	0.02 mg.
Treadwell method.....	0.23 mg.
Liebig-Gauhe method.....	0.09 mg.

These figures do not adequately convey the relative merits of the three methods, for it should be noted that the Liebig-Gauhe method requires a confirmatory test to make the result quite reliable; the Treadwell method failed to show the stated minimum amount of nickel when so little as 231 times as much cobalt as nickel was present; while the silver method appears to retain its full sensitiveness in presence of any amount of cobalt; moreover, it increases the sensitiveness of dimethylglyoxime about eight times and is able to detect within 24 hours less than 0.002 mg. of nickel in a volume of 50 cc.

### Summary.

1. A modified method of using dimethylglyoxime for detecting traces of nickel in cobalt salts is proposed which (a) avoids the use of large amounts of this rather costly reagent; (b) makes possible the detection of considerably smaller quantities of nickel than has been possible heretofore.

2. The sensitiveness of the test is shown to be unaffected by the presence of cobalt even in large quantities. The proposed method increases the ordinary sensitiveness of dimethylglyoxime about eight times and is capable of detecting about one-fifth the amount of nickel detectable by any of the previously known methods.

LAFAYETTE, IND.

---

### NOTE.

**An Apparatus for Determining the Ions in a Solution.**—In the course of certain work which was being conducted in this laboratory, the following apparatus for the determination of the ions into which a solution dissociates was found to work very satisfactorily. The idea is similar to that expressed by Prof. Stieglitz in his *Qualitative Analysis*, Vol. I, page 70.

The apparatus is simple and readily constructed, consisting essentially of a U-tube with a means for closing the two arms and for introducing the substance to be tested into the lowest part of the tube. The center part is made by blowing into a piece of glass tubing of about one-half inch diameter a piece of ordinary sized tubing which has previously been drawn out into a fine jet, and fusing to the other end of this latter a thistle tube carrying a small bore stopcock. The large tube is ridged on either side of the jet tube to prevent lateral flowing of the introduced liquid. The side tubes, which are adapters, are connected with the center tube through large bore stopcocks. If the stopcocks are not handy, the side arms may be connected through rubber tubing bearing pinchcocks, although the use of this necessitates the running of two determinations since closing one side may force the liquid over into the other. Platinum electrodes are used.

In use the apparatus is kept in a bath of continually flowing cold water, the container for which is preferably of glass so that the electrolysis may be more readily watched. The tube is filled with an electrolyte of suitable concentration (0.25 *N* for 110 v. current) and of such a nature that it will not interfere with the results and the electrolysis started. Two cc. or more of the substance to be tested are introduced through the thistle tube and the ac-

tion allowed to run about one-half an hour when the side arms are closed and the contents tested.

For instance, with nitric acid as an electrolyte it can easily be shown after adding copper sulfate that the copper ion migrates to the cathode compartment and the sulfate ion to the anode, or, with calcium chloride that the calcium ion goes toward the cathode and the chloride ion toward the anode. With sodium hydrate as an electrolyte the complex ion of Fehling's solution, containing copper, or, the complex ion containing mercury of a solution of mercuric sulfide in sodium hydrate, probably  $\text{HgS}^{--}$ , migrates toward the anode. It was also used in the determination of the charge on inorganic colloids.

## STUDIES ON CATALYSIS. I. THE ADDITION COMPOUNDS OF ESTERS WITH ORGANIC ACIDS.<sup>1</sup>

BY JAMES KENDALL AND JAMES ELIOT BOOGE.

Received May 29, 1916.

CONTENTS.—1. Introduction. Purpose and Scope of Investigation. 2. Review of Previous Work: (a) The Mechanism of Acid Catalysis of Ester Hydrolysis; (b)

<sup>1</sup> For previous papers on addition compound formation see *THIS JOURNAL*, 36, 1222, 1722, 2498 (1914); 37, 149 (1915); 38, 1309 (1916).

Addition Compound Formation in Systems Ester-Acid. 3. Experimental Procedure. 4. Experimental Data. 5. Relative Stability of Addition Compounds. 6. Compound Formation a General Phenomenon. 7. Structure of Addition Compounds Isolated. 8. Summary.

### 1. Introduction. Purpose and Scope of Investigation.

Few reactions have been more carefully studied than the catalysis of ester hydrolysis by acids. We have at our disposal, from among the multitude of experimental facts recorded, data for all the possible range of conditions—variation of the ester, variation of the acid, variation of temperature, variation of the concentration of ester, of acid, and of water. This being so, it is only natural that there should also exist an accumulation of hypotheses regarding the nature and the mechanism of the reaction. The strange thing is that, in spite of all, few reactions are still so little understood.

The main reason for this unfortunate state of affairs is that theories have always been thrust far in advance of facts, so far indeed that they have often lost touch of them altogether. The experimental data have been systematically overworked in their task of supporting unwieldy masses of premature speculation.

As one possible explanation of the catalysis of ester hydrolysis by acids, the theory of intermediate addition compounds has been advanced, and appears to hold the field at present. The great majority of chemists who have, in recent years, attempted to elucidate the mechanism of the reaction have regarded as the *first step* in the hydrolysis the addition of the acid to the ester to form an oxonium salt.<sup>1</sup> Although a number of papers do not give this first step definitely, the formulation most favored is

The formation of this complex ester-hydrogen-ion  $[\text{R.COO.R}',\text{H}]^+$  necessitates the further assumption that the undissociated compound as given by the equilibrium

must also be present. Until now only a single compound of the suggested type has definitely been isolated. We have therefore no direct proof that such compound formation is a *general phenomenon* in systems of the type ester-acid, and upon this assumption the whole theory rests. Consequently it seemed to the authors especially desirable to investigate *systematically* the general behavior of ester-acid mixtures with respect to compound formation.

The results of this investigation were very gratifying, as thirteen compounds of the type (ester)<sub>m</sub>, (acid)<sub>n</sub> were isolated. Moreover it may be

<sup>1</sup> In this paper the terms "addition compound" and "oxonium salt" are synonymous.

deduced that any ester,  $R.COOR'$ , will combine directly with any acid,  $HX$ , to a greater or less amount, and the main factors governing the extent of addition compound formation are also made clear. By direct isolation of these compounds, which have heretofore merely been *assumed* to exist, strong support is thus given to the theory of intermediate oxonium salt formation in the catalytic hydrolysis of esters by acids.

## 2. Review of Previous Work.

A brief outline of some of the previous work in this field will aid in the consideration of our results.

(a) **The Mechanism of Acid Catalysis of Ester Hydrolysis.**—Various theories have been formulated to explain this phenomenon. The more prominent may be grouped into three classes.

**Class I. Assumption: The Catalyst Acts by its Mere Presence.**—The old view of catalysis was that the acid (hydrogen ion) acted in some mysterious manner, the reaction obediently proceeding with increased velocity.

A rational modification of this view has recently been advanced by Lewis<sup>1</sup> and coworkers. It is assumed that the (hydrated) methyl acetate molecule absorbs quanta of radiation in the infra-red region, sent out by the (hydrated) hydrogen ion, the consequent addition of energy to the ester molecule inducing great instability or chemical activity. This view is appealing in its simplicity but has not been sufficiently developed experimentally to judge whether it can explain the complicated relations holding between velocity of hydrolysis and concentration of the reacting substances. Moreover, it simply postulates the *driving force* which increases the velocity of the reaction without accounting for the mechanism or stages in which the reaction takes place.<sup>2</sup>

**Class II. Assumption: Direct Ionization of Organic Compounds.**—This was the natural outgrowth of the too enthusiastic application of the ionic theory. Direct ionization of the ester to  $R.COO^-$  and  $R'^+$  was postulated by Zengelis<sup>3</sup> and to  $RCO^+$  and  $OR'^-$  by Euler.<sup>4</sup> Increased concentration of hydrogen ion would tend to remove one of the ions in each case, accelerating the hydrolysis of the ester. The decreased concentration of hydroxide ion would, however, simultaneously have the opposite effect. Due to the lack of verification of such ionizations and to the incorrect quantitative results<sup>5</sup> to which they lead, these views have been discarded.

<sup>1</sup> *J. Chem. Soc.*, 105, 2330 (1914); 107, 233 (1915); 109, 55, 67 (1916).

<sup>2</sup> In any metathesis there are necessarily but two possible mechanisms—either decomposition of  $AB$  and  $CD$  followed by combination of the parts, or intermediate combination to  $AB.CD$  followed by decomposition in another way. Both of these views have been advanced in ester hydrolysis (See II and III).

<sup>3</sup> "On Chemical Affinity," Athens, 1896, *Ber.*, 34, 198 (1901).

<sup>4</sup> *Z. physik. Chem.*, 36, 640 (1901).

<sup>5</sup> Stieglitz, *Am. Chem. J.*, 39, 404, 423 (1908).

**Class III. Assumption: Intermediate Addition Compounds are Formed.**—Kastle,<sup>1</sup> in a paper read before the A. A. A. S. in 1896, first suggested the possibility that an "addition product" of the ester and catalyzing acid might be formed. His formulation of the reaction

is undoubtedly incorrect, assuming as it does greater concentration of oxonium base in a more strongly acid solution. Bredig<sup>2</sup> suggested, in 1903, and again in 1904, that the complex ion  $[\text{R.COO.R'}, \text{H}]^+$  may be active in the hydrolysis of esters. Lapworth, in 1904 (Mellor's "Statics and Dynamics," p. 289), gave a more complete formulation of the hydrolysis in the presence of an acid. This view has likewise been severely criticized and has no experimental evidence in its support.<sup>3</sup> Acree,<sup>4</sup> Rosanoff,<sup>5</sup> Falk and Nelson,<sup>6</sup> and numerous other chemists have assumed the formation of intermediate addition compounds, the last named authors applying the electron conception of valence, without however considering the subject quantitatively.

Stieglitz<sup>7</sup> has treated the whole problem from a quantitative standpoint, starting from the fact that a possible mechanism for the catalysis is

From this there is deduced the expression for the velocity of hydrolysis

$$\frac{dx}{dt} = K_s \cdot C_{\text{ester}} \cdot C_{\text{H}^+} \cdot C_{\text{H}_2\text{O}}$$

This was at the time supposed to represent the experimental facts, but in the light of more recent work becomes a rough approximation only. Thus

<sup>1</sup> Stieglitz, *Am. Chem. J.*, 39, 421 (1908).

<sup>2</sup> *Z. Electrochem.*, 9, 118 (1903); 10, 586 (1904).

<sup>3</sup> Stieglitz, "International Congress of Arts and Sciences" at St. Louis, 4, 278 (1904); *Am. Chem. J.*, 39, 424 (1908).

<sup>4</sup> *Am. Chem. J.*, 48, 352 (1912).

<sup>5</sup> *This Journal*, 35, 173 (1913).

<sup>6</sup> *Ibid.*, 37, 1732 (1915).

<sup>7</sup> *Am. Chem. J.*, 39, 29, 60 (1908).

it has been demonstrated within the last few years that the velocity,  $-dx/dt$ , increases *more rapidly* than  $C_{\text{ester}}$  or  $C_{\text{H}^+}$ , *i. e.*, increase in the concentration of water (dilution of the solution) causes more of a retardation than that calculated by the law of mass action.<sup>1</sup>

To explain the abnormal acceleration of hydrolysis with increase of  $C_{\text{H}^+}$  several theories have been advanced, notably the theory of the negative catalytic effect of water and the theory that the undissociated acid molecules,  $\text{HX}$ , are also catalytically active. These theories, together with the bearing of the results of the present paper upon them, will be examined in a subsequent communication.

From the foregoing discussion it will be apparent that the catalytic activity of acids has not been satisfactorily explained in a quantitative way—and that this can scarcely be expected until the complete mechanism of the reaction is rigorously established.

(b) **Addition Compound Formation in Systems Ester-Acid.**—The *experimental* evidence of the existence of such compounds is very unsatisfactory.

Lewis has recently<sup>2</sup> advanced the hypothesis that an *ester-water* compound  $\text{R.COO.R'}. \text{HOH}$  is active in hydrolysis. Absorption in the infra-red region is the only evidence brought forward that such compounds exist. A compound of this type has never been isolated and moreover the work of Rivett<sup>3</sup> indicates that such a compound does not exist, to any appreciable extent, in an aqueous solution of ethyl acetate. From his results for the freezing-point depression of water by this ester, *recalculated to weight concentrations*,<sup>4</sup> it is seen that the depression is exactly linear; hence no combination, or at most only a minute trace, occurs.

On the other hand, the results of the present paper definitely establish the existence of binary compounds, *ester-acid*. Previous evidence on this question is almost entirely indirect. Thus the increasing molecular conductivity with increase of concentration of esters dissolved in liquid hydrogen halides is taken as being due to combination followed by ionization.<sup>5</sup> Many classes of organic oxygen compounds, as alcohols, acids, phenols, ketones, etc., form oxonium salts with various inorganic and organic acids; esters would be expected to form analogous compounds. The validity of such indirect evidence is, however, always open to suspicion and cannot have the same weight as the actual isolation of the compounds in question.

<sup>2</sup> *Ibid.*, 109, 80 (1916).

<sup>3</sup> *Z. physik. Chem.*, 80, 547 (1912).

<sup>4</sup> Noyes and Falk, *THIS JOURNAL*, 32, 1013 (1910).

<sup>5</sup> Walker, McIntosh and Archibald, *J. Chem. Soc.*, 85, 1100 (1904).

**Direct Evidence.**—Baeyer and Villiger<sup>1</sup> obtained "compounds" of  $\text{H}_3\text{Fe}(\text{CN})_6$  with ethyl acetate, ethyl benzoate and diethyl oxalate and of  $\text{H}_4\text{Fe}(\text{CN})_6$  with diethyl oxalate. Some uncertainty is introduced into the assumption that these are actually compounds by the work of McIntosh,<sup>2</sup> who conclusively proved that Baeyer and Villiger's "compounds" of ether and of acetone with  $\text{H}_4\text{Fe}(\text{CN})_6$  are in reality solid solutions. The only definite isolation of oxonium compounds of an ester with an acid is given by Maass and McIntosh,<sup>3</sup> who completely investigated the system, ethyl acetate-hydrogen chloride. The compounds formed were  $\text{CH}_3\text{COO.C}_2\text{H}_5\text{HCl}$ ;  $\text{CH}_3\text{COO.C}_2\text{H}_5\text{HCl}$ ; and  $2\text{CH}_3\text{COO.C}_2\text{H}_5\text{HCl}$ .

### 3. Experimental Procedure.

The complete examination of 22 ester-acid systems has been accomplished by the freezing-point method previously described. A number of mixtures of known composition are successively prepared for a binary system and the freezing point, *i. e.*, the temperature at which a minimum (negligible) amount of solid is in *equilibrium* with the liquid phase, is taken for each mixture. A series of such points determines the temperature-composition curve. In the diagram so obtained a break in the curve indicates a change in the solid phase crystallizing out. A maximum point indicates a compound, the position of the maximum with reference to the molecular composition axis gives the formula of the compound and the slope of the curve around the maximum indicates the extent of dissociation of the compound into its components, here ester and acid. For further details previous papers of this series should be consulted.<sup>4</sup>

The behavior of systems of the type  $\text{R.COO.R}'\text{-HX}$  will be dependent upon the character of the three radicals R, R' and X.<sup>5</sup> In order to make our conclusions as general as possible, all three radicals have been widely varied in the different systems examined.

The acids, HX, employed were trichloroacetic (the strongest of the simple organic acids), chloroacetic (a typical transition acid), and acetic (a typical weak acid). Esters of both monobasic and dibasic aliphatic and aromatic acids were chosen, the acids varying in strength from acetic to oxalic. The third radical, R', was varied by working with ethyl, methyl, benzyl, phenyl, and  $\alpha$ - and  $\beta$ -naphthyl esters. The following table gives the dissociation constants of the acids used and of the acids from which the esters were derived:

<sup>2</sup> *THIS JOURNAL*, **30**, 1097 (1908).

<sup>3</sup> *Ibid.*, **34**, 1288 (1912).

<sup>4</sup> Kendall, *Ibid.*, **36**, 1225 (1914).

<sup>5</sup> Kendall and Gibbons, *THIS JOURNAL*, **37**, 159 (1915).

TABLE I.—DISSOCIATION CONSTANTS OF ACIDS.<sup>1</sup>

	100 K.		100 K.
Trichloroacetic.....	121.0	Salicylic.....	0.102
Monochloroacetic.....	0.155	Benzoic.....	0.0060
Acetic.....	0.0018	$\alpha$ -Toluic.....	0.00556
		<i>p</i> -Toluic.....	0.00515
Oxalic.....	10.0	Cinnamic.....	0.00355
Malonic.....	0.158	Anisic.,.....	0.0032
Succinic.....	0.00665	Terephthalic.....	0.015 (approx.)

From previous work on binary mixtures<sup>2</sup> the following relations are to be expected:

(1) **Varying X.**—Strong acids should give marked compound formation, with the possibility of isolating the compounds; weak acids, on the other hand, should exhibit less combination.

(2) **Varying R.**—Compound formation should be less for derivatives of strong than for those of weak acids. Making R more "negative" (as in passing from ethyl acetate to ethyl benzoate) should decrease the amount of combination.

(3) **Varying R'.**—As R' becomes more "negative" (for example, as we pass from phenyl benzoate to ethyl benzoate) the ester should exhibit less compound formation with acids. Thus the "basic properties" (tendency to form onium compounds) of the ester oxygen atoms should be repressed by the proximity of "negative" groups.

These expectations were indeed realized, as will be shown in Section 5. The views in regard to the relative stability of oxonium compounds put forward in previous papers of this series have thus received further confirmation.

**Measurement of Temperatures.**—Above  $-35^{\circ}$  several mercury thermometers with convenient ranges of scale, graduated in tenths, were used. These were calibrated as usual at  $0^{\circ}$  and  $100^{\circ}$  and also compared with certified thermometers. The toluene thermometer employed for temperatures below  $-35^{\circ}$  was accurate down to  $-35^{\circ}$  by calibration with a certified mercury thermometer. At  $-78.2^{\circ}$  ( $\text{CO}_2$ -alcohol paste) and  $-82.8^{\circ}$  (m. p. of pure ethyl acetate)<sup>3</sup> it was still accurate to within  $\pm 1^{\circ}$ .<sup>4</sup>

The melting points given are corrected as usual for exposed stem. The stem correction for the toluene thermometer was so large ( $7-8^{\circ}$ ) that it was deemed safer to determine it directly than to use the coefficient of expansion of toluene, which varies with the temperature. The stem

<sup>1</sup> Ostwald, *Z. physik. Chem.*, **3**, 377, 418 (1889).

<sup>2</sup> Kendall, *Loc. cit.*

<sup>3</sup> Guttman, *THIS JOURNAL*, **29**, 345 (1907).

<sup>4</sup> A greater accuracy at these temperatures is very difficult to obtain. See Guttman, *Loc. cit.*, and Beckmann and Waentig, *Z. anorg. Chem.*, **69**, 17 (1910).

corrections found experimentally at a number of temperatures were plotted and used in correcting observed melting points between  $-35^{\circ}$  and  $-100^{\circ}$ .

The temperatures given later in the tables may be taken as having the following degree of accuracy:

Temperatures from $150^{\circ}$ to $100^{\circ}$	Possible error $0.2-0.5^{\circ}$
Temperatures from $100^{\circ}$ to $-10^{\circ}$	Possible error $0.1-0.2^{\circ}$
Temperatures from $-10^{\circ}$ to $-35^{\circ}$	Possible error $0.2-0.5^{\circ}$
Temperatures from $-35^{\circ}$ to $-100^{\circ}$	Possible error $1.0-2.0^{\circ}$ (usually $\pm 1^{\circ}$ )

A somewhat greater comparative accuracy for points on the same curve was attained, as is evidenced also by the smoothness of the curves.

For cooling below  $-20^{\circ}$  carbon dioxide snow and acetone were used, and for temperatures below  $-80^{\circ}$ , liquid air. Supercooling of the mixtures was quite general. To induce a compound to crystallize when no solid was available for seeding, it was often necessary to cool the mixture some  $50^{\circ}$  below the freezing point (to a glass), and allow it to warm slowly, vigorously scratching the walls of the tube. After several hours' repetition of this procedure the compound could usually be persuaded to crystallize out.

In all cases the melting point was determined by warming the partially frozen mixture very slowly and observing the temperature at which the last traces of crystals were *just in equilibrium* with the liquid, *i. e.*, the true temperature of incipient freezing. Points on a curve could be duplicated with a separate mixture of the same composition to within the limits of experimental error. Likewise even after it had stood for several days with the exclusion of moisture a given mixture exhibited the same melting point as immediately after mixing. This proves that the formation of the addition compound is not a time reaction, but is practically instantaneous even at temperatures below  $-50^{\circ}$ .

In the following tables, as elsewhere in the paper, the composition of every mixture is expressed in *molecular* percentages.

#### 4. Experimental Data.

**A. Systems with Trichloroacetic Acid.**—Trichloroacetic acid, after prolonged desiccation over sulfuric acid, *in vacuo*, gave a melting point of above  $58^{\circ}$  ( $55^{\circ}$  in literature).

**1. Ethyl Acetate.**—The ethyl acetate used was a pure commercial sample, washed with water and carefully fractionated after standing over calcium chloride. It froze at a constant temperature of  $-83^{\circ} \pm 1^{\circ}$ . The compound,  $\text{CH}_3\text{COO.C}_2\text{H}_5\text{CCl}_3\text{COOH}$ , was obtained, crystallizing in large glistening plates, melting at  $-27.5^{\circ}$ .

(a) Solid Phase,  $\text{CH}_3\text{COO.C}_2\text{H}_5$ .

Per cent. ester.....	100	95.5
Temp.....	$-83.0$	$-88.0$

(b) Solid Phase,  $\text{CH}_3\text{COO.C}_2\text{H}_5\text{CCl}_3\text{COOH}$ .

Per cent. ester.....	87.1	78.9	70.5	59.9	50.0	47.8	45.3
Temp.....	-70.5	-53.0	-42.0	-32.5	-27.5	-28.1	-28.9

(c) Solid Phase,  $\text{CCl}_3\text{COOH}$ .

Per cent. ester.....	40.1	32.7	24.6	17.6	8.5	0	
Temp.....	-18.3	10.7	30.4	42.8	52.3	58.8	

2.  $\alpha$ -Naphthyl Acetate.—This ester was prepared from acetyl chloride and  $\alpha$ -naphthol, the product being decolorized with animal charcoal, recrystallized three times from alcohol and finally from  $\text{CCl}_4$ . The compound  $\text{CH}_3\text{COO.C}_{10}\text{H}_7\text{CCl}_3\text{COOH}$ , crystallizing in prismatic needles and melting at  $10.7^\circ$ , was isolated.

(a) Solid Phase,  $\text{CH}_3\text{COO.C}_{10}\text{H}_7$ .

Per cent. ester.....	100	90.4	82.3	76.0	69.6	64.0	58.6
Temp.....	44.8	40.0	34.8	29.7	23.6	16.5	7.5

(b) Solid Phase,  $\text{CH}_3\text{COO.C}_{10}\text{H}_7\text{CCl}_3\text{COOH}$ .

Per cent. ester.....	54.3	50.1	46.2	40.7	35.4		
Temp.....	10.0	10.7	10.2	8.0	6.0		

(c) Solid Phase,  $\text{CCl}_3\text{COOH}$ .

Per cent. ester.....	30.0	23.3	15.5	8.1	0		
Temp.....	21.0	33.5	44.5	51.9	58.0		

3.  $\beta$ -Naphthyl Acetate.—This ester, after preparation from  $\beta$ -naphthol and acetic anhydride, was, with difficulty, purified by repeated rapid recrystallization from alcohol. The work was carried out below  $0^\circ$  to retard hydrolysis. An equimolecular compound with a rather high melting point ( $66.3^\circ$ ) was obtained, crystallizing in thin, oblong plates. (See Curve V, Fig. 1.)

(a) Solid Phase,  $\text{CH}_3\text{COO.C}_{10}\text{H}_7$ .

Per cent. ester.....	100	89.9	82.4		
Temp.....		68.5	63.9	59.4	

(b) Solid Phase,  $\text{CH}_3\text{COO.C}_{10}\text{H}_7\text{CCl}_3\text{COOH}$ .

Per cent. ester.....	71.1	65.2	60.1	55.1	50.0
Temp.....	55.5	60.9	63.6	65.4	66.3
Per cent. ester.....	45.6	43.0	38.1	32.4	24.5
Temp.....	65.7	64.8	62.3	57.7	48.7

(c) Solid Phase,  $\text{CCl}_3\text{COOH}$ .

Per cent. ester.....	16.1	8.6	0		
Temp.....	43.8	51.5	58.2		

4. Ethyl Benzoate.—A pure sample was fractionated and the portion boiling between  $208.3^\circ$  and  $208.6^\circ$  used. This gave a melting point of  $-32.7^\circ$  (not previously determined). A second crystalline form (m. p.  $-40^\circ$ ) was also found to exist. (Compare methyl benzoate.) A compound,  $\text{C}_6\text{H}_5\text{COO.C}_2\text{H}_5\text{CCl}_3\text{COOH}$ , crystallizing in sheaves of needles, was isolated; m. p.  $-23.4^\circ$ .

(a) Solid Phase,  $C_6H_5.COO.C_2H_5$ .

Per cent. ester.....	100	87.7	78.8
Temp.....	—32.7	—38.4	—45.0

(b) Solid Phase,  $C_6H_5.COO.C_2H_5.CCl_3.COOH$ .

Per cent. ester.....	71.0	64.4	61.1	54.4	50.0	47.3	45.2
Temp.....	—38.5	—31.6	—28.5	—24.7	—23.4	—23.5	—24.0

(c) Solid Phase,  $CCl_3.COOH$ .

Per cent. ester.....	40.7	35.3	29.8	24.4	19.7	14.0	7.2	0
Temp.....	—10.1	6.0	20.0	30.5	38.5	46.2	53.2	58.7

**5. Methyl Benzoate.**—The methyl benzoate was prepared as usual from benzoic acid and absolute methyl alcohol by saturation with hydrogen chloride. The fraction boiling constantly at  $197.8^\circ$  gave a melting point of  $-12.3^\circ$  (not previously determined). A metastable crystalline form also exists with m. p.  $-13.7^\circ$ . This gives rise to a second melting-point curve paralleling that of the stable form. An equimolecular compound (also existing in two crystalline modifications, m. p.  $-10.6^\circ$  and  $-8.8^\circ$ , both crystallizing in needles) was isolated. (See Curve II, Fig. 1.)

(a) Solid Phase,  $C_6H_5.COO.CH_3$ .

## Metastable Form.

Per cent. ester..	100	95.7	94.0	92.9
Temp.....	—13.7	—15.0	—16.3	—17.0

## Stable Form.

Fig. 1.—Freezing-point curves of esters of monobasic acids with trichloroacetic acid.

- I. Ethyl acetate (scale correct).  
 II. Methyl benzoate (subtract 20°).  
 III. Methyl cinnamate (subtract 50°).  
 IV. Phenyl benzoate (subtract 90°).  
 V.  $\beta$ -Naphthyl acetate (subtract 130°).

**7. Methyl Anisate.**—Methyl anisate was prepared from anisic acid, absolute methyl alcohol and sulfuric acid by refluxing. The product, recrystallized from methyl alcohol by cooling to 0°, gave a m. p. of 48.3° (45–46° in literature). A compound,  $\text{CH}_3\text{O.C}_6\text{H}_4.\text{COO.CH}_3.\text{CCl}_3\text{COOH}$ , crystallizing in small, glittering plates, m. p.  $-6.3^\circ$ , was isolated. This compound also crystallized in a metastable form of lower melting point.

(a) Solid Phase,  $\text{CH}_3\text{O.C}_6\text{H}_4.\text{COO.CH}_3$ .

Temp.....	-6.5	5.0	17.0	31.5	41.1	50.6	58.1

**8. Methyl Cinnamate.**—Methyl cinnamate (prepared by passing hydrogen chloride into a solution of cinnamic acid in absolute methyl alcohol) was recrystallized from alcohol with the addition of water until turbid, followed by cooling on ice. The ester showed no test for chlorine and melted at  $34.7^\circ$  ( $33^\circ$  in literature). With trichloroacetic acid an equimolecular compound, crystallizing in slender needles, was obtained. That the double bond has nothing to do with the formation of this compound is evidenced by the fact that HCl does *not* add on *permanently* during the preparation of the ester.<sup>1</sup> (See Curve III, Fig. 1.)

(a) Solid Phase,  $\text{C}_6\text{H}_5.\text{CH}:\text{CH}.\text{COO.CH}_3$ .

Temp.....	6.5	17.8	30.0	41.9	50.4	58.3

**9. Methyl *p*-Toluate.**—The ester was prepared from *p*-toluic acid dissolved in absolute methyl alcohol and saturated with hydrogen chloride. After several recrystallizations from diluted methyl alcohol the ester melted at  $33.2^\circ$  ( $32^\circ$  in literature). A compound crystallizing in rectangular plates, m. p.  $9^\circ$ , was obtained.

(a) Solid Phase,  $\text{CH}_3\text{C}_6\text{H}_4.\text{COO.CH}_3$ .

Temp.....	11.0	28.6	43.1	52.0	59.2

<sup>1</sup> The addition of HCl at the double bond would give a stable saturated compound not again decomposed by addition of water as are the oxonium compounds. Also here, as in previous work, the cinnamic acid behaves normally with respect to stability of the compound, etc.—the double bond having no apparent effect. No compound could be isolated with chloroacetic acid. (See System 20, below.)

**10. Phenyl Benzoate.**—The phenyl benzoate was prepared by the Schotten-Baumann reaction and purified by several recrystallizations from alcohol. No compound could be isolated, but the slope of the curve shows much compound formation in the liquid phase. (See Curve IV, Fig. 1.)

(a) Solid Phase,  $C_6H_5.COO.C_6H_5$ .

Per cent. ester.....	100	87.4	78.4	70.9	64.5	52.7	50.2	43.8	40.3
Temp.....	67.8	62.8	57.3	52.1	46.7	33.0	29.6	19.0	13.2

(b) Solid Phase,  $CCl_3.COOH$ .

Per cent. ester.....	35.0	30.7	23.3	15.2	8.0	0			
Temp.....	11.5	21.0	33.7	44.7	52.1	58.5			

**11. Phenyl Salicylate.**—A commercial specimen of satisfactory m. p. was employed. Although no compound could be isolated, yet the form of the curve (see later) again indicated much combination in the liquid phase.

(a) Solid Phase,  $HO.C_6H_4.COO.C_6H_5$ .

Per cent. ester.....	100	95.1	87.9	84.3	80.4	76.3

Temp.....	27.5	23.8	21.6	15.8	8.0				

(b) Solid Phase,  $CCl_3.COOH$ .

Per cent. ester.....	19.8	14.2	8.2	0					
Temp.....	39.5	45.4	51.7	57.9					

**12. Diethyl Succinate.**—A specimen from a well-known manufacturer, after fractionation, gave a m. p. of  $-20.8^\circ$ , identical with that given in the literature. The central portion of the curve could not be completed, as mixtures in this region refused to crystallize even after standing for some time in liquid air. However, the form of the curve (as far as it could be traced) leaves little reason for doubt that the compound  $C_2H_4(COO.C_2H_5)_2, 2CCl_3.COOH$  is present in the liquid mixture (compare dimethyl succinate below). (See Curve III, Fig. 2.)

(a) Solid Phase,  $C_2H_4(COO.C_2H_5)_2$ .

Per cent. ester.....	100	90.8	82.7	75.1	67.3	59.8

Temp.....	7.1	8.0	7.0	5.5			

(c) Solid Phase,  $CCl_3.COOH$ .

Per cent. ester.....	23.2	15.8	8.6	0
Temp.....	17.7	37.2	49.7	58.1

**14. Dimethyl Malonate.**—The ester was prepared in the usual manner, the product being finally fractionated *in vacuo*. The ester has not previously been frozen (m. p.  $-62^\circ$ ). Owing to supercooling with formation of glasses, mixtures containing between 60% and 100% of ester could not be examined. (The probable form of the curve is indicated by a broken line in Curve I, Fig. 2.)

A compound crystallizing in plates was isolated. It is unstable at its maximum but obviously, from the form of the curve near the break, is the compound  $CH_2(COO.CH_3)_2, 2CCl_3.COOH$  (compare Systems 12 and 13); m. p.  $-28.5$  (by extrapolation).

(a) Solid Phase,  $CH_2(COO.CH_3)_2$ .

Per cent. ester.....	100
Temp.....	$-62.0$

(b) Solid Phase,  $CH_2(COO.CH_3)_2, CCl_3.COOH$ .

Per cent. ester.....	60.9	54.4	50.0	45.8	41.7	37.8
Temp.....	-60.0	-46.1	-39.0	-34.0	-31.0	-29.2

Fig. 2.—Freezing-point curves of esters of dibasic acids with trichloroacetic acid.

- I. Dimethyl malonate (scale correct). IV. Dimethyl succinate (subtract  $120^\circ$ ).  
 II. Diethyl oxalate (subtract  $40^\circ$ ). V. Dimethyl terephthalate (subtract  $140^\circ$ ).  
 III. Diethyl succinate (subtract  $90^\circ$ ).

**17. Dimethyl Terephthalate.**—A pure specimen of the ester (m. p. 140.3) was furnished by Mr. C. P. Harris. This system is especially interesting, due to the fact that a compound,  $C_6H_4(COO.CH_3)_2,4CCl_3.COOH$ , was isolated. It would be expected by analogy to dimethyl malonate and succinate that only a compound  $AB_2$  should be formed. It is probable that a compound  $AB_2$  exists but its curve never enters the stable region.

As will be seen from Curve V, Fig. 2, the compound  $AB_4$  is only just stable at its maximum (m. p. 27.9°); it was consequently deemed advisable to analyze it. This was done by filtering and drying the large needles of the compound at a temperature of between 25° and 26°. The extremely hygroscopic crystals were weighed and added to water, whereby the compound was decomposed into its components. The acid was then titrated.

0.4563 g. crystals required 12.80 cc. 0.1683 normal NaOH. Found: 0.3520 g. trichloroacetic acid. Calc. for 1 : 4 compound: 0.3519 g.

Per cent. ester.....	32.7	22.9	17.7	6.1	0.0		
Temp.....	-5.3	1.4	5.2	12.7	16.4		

From the preceding data it will be seen that, in each of the thirteen compounds isolated, trichloroacetic acid was the acid component. In no case did the weaker chloroacetic and acetic acids combine with the ester to a sufficient extent to allow a compound to be isolated. Likewise, the esters *not* yielding compounds with trichloroacetic acid are those of strong acids (dimethyl oxalate) or phenyl esters of moderately strong acids (phenyl benzoate and salicylate).

**5. Relative Stability of Addition Compounds.**

With regard to the relative stability of the oxonium salts obtained (*i. e.*, the extent of the combination of ester and acid in the liquid phase, as discussed on p. 1718), two lines of evidence may be brought forward.

(a) **Sharpness of Maxima.**—The addition compounds isolated are all more or less dissociated into their components in the liquid state. Their stability may be approximately determined from the sharpness of the maximum,<sup>1</sup> *i. e.*, the decrease in the temperature of fusion of the compound on addition of either component. The less the depression, or the flatter the curve in the neighborhood of the maximum, the greater is the dissociation at the melting point as expressed by the equation

In the following table some freezing-point lowerings for the compounds of trichloroacetic acid with esters are compared.

<sup>1</sup> Kendall, *Loc. cit.* See also Kremann, *Monatshefte*, 25, 1215 (1904).

TABLE II.—FREEZING-POINT DEPRESSIONS OF COMPOUNDS OF TRICHLOROACETIC ACID WITH ESTERS ON ADDITION OF EITHER COMPONENT.

System and type of compound. (A = ester. B = acid.)			Depression of freezing point ( $\Delta T$ ).	
			(a) 5 mol % from maximum.	(b) 10 mol % from maximum.
1. Ethyl acetate	AB.....	—27.5°	1.5°	5.2° <sup>2</sup>
2. $\alpha$ -Naphthyl acetate	AB.....	10.7	0.9	2.8 <sup>2</sup>
3. $\beta$ -Naphthyl acetate	AB.....	66.3	0.8	2.7
4. Ethyl benzoate	AB.....	—23.4	1.2	4.4 <sup>2</sup>
5. Methyl benzoate	AB.....	—8.8	1.1	4.2 <sup>2</sup>
6. Benzyl benzoate	AB.....	11.9	0.9	2.7
7. Methyl anisate	AB.....	—6.3	0.9	3.5 <sup>2</sup>
8. Methyl cinnamate	AB.....	8.5	1.5	5.3
9. Methyl <i>p</i> -toluate	AB.....	9.0	1.1	4.1
13. Dimethyl succinate	AB <sub>2</sub> .....	8.0	1.6 <sup>2</sup>	4.8 <sup>2</sup>
14. Dimethyl malonate	AB <sub>2</sub> .....	—28.2 <sup>3</sup>	1.02 <sup>2,3</sup>	4.02 <sup>2,3</sup>
15. Diethyl oxalate	AB <sub>2</sub> .....	3.4	1.2 <sup>2</sup>	3.8 <sup>2</sup>

For esters of monobasic acids (1 to 9), Column 4 gives the mean depression resulting from the addition of sufficient ester or acid to give a mixture containing, respectively, 55 or 45 molar per cent. of ester. Similarly, Column 5 gives the mean depression for mixtures containing 60 and 40 molar per cent. ester. For esters of dibasic acids (13–15) 61<sup>2</sup>/<sub>3</sub> and 56<sup>2</sup>/<sub>3</sub> molar per cent. of ester are chosen.

This method gives only an *approximate* indication of the relative stability of compounds of different esters with trichloroacetic acid. First of all the comparisons are not made at the same temperature, and secondly, the heat of fusion of the complex, related as it is to the freezing-point lowering, ought to be taken into consideration. Nevertheless, that the method is of value in affording qualitative relationships is evident from the following examples.

A sharper maximum, indicating greater stability, is obtained with the ethyl acetate compound than with the  $\alpha$ - or  $\beta$ -naphthyl acetates. So also is the depression somewhat greater for ethyl than for methyl benzoate and for these in turn markedly greater than in the case of benzyl benzoate. When we compare the methyl esters, the order of stability of the compounds becomes methyl cinnamate > methyl benzoate (or *p*-tolu-

<sup>1</sup> There is but little regularity in the melting points of the compounds isolated. They fall below or between those of the components. McIntosh's rule that the melting point of an oxonium compound is above that of either component is not general, but holds only for compounds with the low-melting hydrogen halides. In some cases the rule fails even here, as with C<sub>6</sub>H<sub>7</sub>OH, 2 HBr and C<sub>6</sub>H<sub>7</sub>OH, 5HCl, which melt lower than the respective hydrogen halides. (Archibald and McIntosh, *J. Chem. Soc.*, **85**, 928 (1904).)

<sup>2</sup> Depression caused by one component only.

<sup>3</sup> Obtained by a short extrapolation. Results are not included where extrapolation would be too great for accuracy.

ate) $>$ methyl anisate.<sup>1</sup> Likewise ethyl acetate exhibits a sharper maximum than ethyl benzoate. These relations are all to be expected from the comparative dissociation constants of the acids (see p. 1718). It is apparent from the above examples that the stability of the complex is greater for esters of weaker acids and where R' is more "positive" (*i. e.*,  $\text{C}_2\text{H}_5 > \text{CH}_3 > \text{C}_6\text{H}_5, \text{CH}_2$ , etc.). For esters of the dibasic acids the same rule holds, as will also be more clearly indicated by Method B below.

The quantitative investigation of the degree of dissociation of these compounds into the components, acid + ester, will be given in a later contribution.

(b) **Relative Slope of Curves.**—Addition compounds may be formed in the liquid phase and yet not be induced to crystallize out, especially if the degree of dissociation into the components at the melting point is large. In such cases, however, the extent of compound formation can be deduced from the change in slope of the freezing-point curve of either component. This gives, indeed, a more *general* method of detecting compound formation<sup>2</sup> than the actual isolation of the products.

On addition of any second substance, B, to a pure substance, A, the resultant lowering of the freezing point of A depends upon the molar fraction of the solute, B, present. If no combination of B with A occurs, the depression of the freezing point is expressed by the equation<sup>3</sup>

$$-\log x = \frac{Q}{RT_0} \left( \frac{T_0}{T} - 1 \right)$$

(where  $x$  = mol. fraction of A in mixture;  $Q$  = mol. heat of fusion of A;  $T_0$  = temperature of fusion of A;  $T$  = temperature of fusion of mixture;  $R = 1.988$ ). The form of this curve varies greatly with the relative values of  $Q$  and  $T_0$ . For organic compounds, in general, the values of  $Q$  and  $T_0$  are such that the ideal curve is, for the greater part of its length, approximately a straight line.

If, however, the addition of a foreign substance, B, to A is accompanied by the formation of an addition compound, AB, then the freezing point of A will be abnormally lowered, since part of the original solvent has been replaced by the second foreign substance AB. The more stable the compound is, the greater will be the abnormal depression of the freezing point. Hence the deviations from the ideal curve when different substances are added to A indicate the relative extent of combination in each case.

<sup>1</sup> Methyl anisate is an apparent exception to the general rule, as anisic acid being weaker than even cinnamic its ester should yield a compound *more* stable than that of the methyl cinnamate. That this is due to one of the factors making this but an approximate method is evidenced by the fact that methyl anisate shows a normal behavior by Method B, following.

<sup>2</sup> Kendall, *THIS JOURNAL*, 36, 1731 (1914).

<sup>3</sup> Roozeboom, *Heterogene Gleichgewichte*, 2, p. 273.

To establish the ideal curve for trichloroacetic acid it was examined with benzene, a substance with which it exhibits no compound formation. This is shown by the following table and more strikingly in Curve I, Fig. 3.

Fig. 3.—Freezing-point depressions of trichloroacetic acid with esters of dibasic acids (solid phase trichloroacetic acid throughout).

- I. Benzene.  
 II. Dimethyl oxalate.

Temp.....	5.4	1.5	—0.5

(b) Solid Phase,  $CCl_3.COOH$ .

Per cent. $C_6H_6$ .....	76.4	68.6	62.7	55.6	
Temp.....	—3.8	3.0	9.4	16.1	
Per cent. $C_6H_6$ .....	47.2	35.2	25.5	16.4	0
Temp.....	23.1	33.0	39.6	46.8	57.2

The comparison of this ideal freezing-point-depression curve for trichloroacetic acid with those caused by esters of various dibasic acids is shown in Fig. 3. Each of these esters lowers the temperature of fusion of trichloroacetic acid much more than does benzene, signifying extensive combination. If the reaction is represented as

each mol of ester on combination removes two mols of solvent. Consequently the dip of the curve is more decided than when an equimolecular compound is formed.

The "falling away" of the curve is greatest with diethyl succinate. The divergences assume the following order: diethyl succinate > dimethyl succinate > dimethyl malonate > diethyl oxalate > dimethyl oxalate. The following conclusions may be drawn: (1) Esters of the stronger acids combine less than esters of the weaker acids. (2) The diethyl ester of succinic or oxalic acid exhibits more combination than the corresponding dimethyl ester (the ether radical being somewhat more "positive" than the methyl radical).

The monobasic acid esters follow the same rules, confirming the results of Method A. This is shown in the table below, where freezing-point depressions of trichloroacetic acid due to 30 or 40 mol % of ester are compared.

TABLE III.—FREEZING-POINT DEPRESSIONS OF TRICHLOROACETIC ACID CAUSED BY ADDITION OF (a) 30 MOL %; (b) 40 MOL % OF AN ESTER.

As an example of the application of these data, the extent of compound

<sup>1</sup> Obtained by short extrapolation, the maximum uncertainty being indicated.

formation for the esters of benzoic acid is seen to be ethyl>methyl>benzyl>phenyl. Similarly methyl anisate manifests more combination than methyl cinnamate, benzoate, etc.<sup>1</sup> Other comparisons are readily made.

## 6. Compound Formation a General Phenomenon.

It has been established above that compound formation is general in systems containing trichloroacetic acid as acid component even in cases where no compound can actually be isolated. The same method may be employed to test the extent of compound formation in the similar systems (Nos. 18 to 22 above) containing weaker acids. We have here a means for determining the effect of variation of the third radical, X. At the same time we may compare the ideal curves for chloroacetic and acetic acids with those obtained on addition of different esters, and discover whether in these cases also general compound formation is indicated.

The normal curves for chloroacetic and acetic acids are established in the following tables:

### 24. Chloroacetic Acid-Benzene.—

(a) Solid Phase,  $C_6H_6$ .

Per cent. $C_6H_6$ ....	100	98.3
Temp.....	5.4	4.8

(b) Solid Phase,  $CH_2Cl.COOH$ .

Per cent. $C_6H_6$ ....	95.0	91.4	89.0	80.6	75.7	70.0	64.4	57.4	47.0	39.4
Temp.....	3.8	10.8	15.9	27.6	31.3	34.7	37.5	40.2	44.1	46.5
Per cent. $C_6H_6$ ....	30.9	24.9	18.3	8.7	0					
Temp.....	49.7	52.0	54.2	57.8	61.4					

### 25. Acetic Acid-Benzene.<sup>2</sup>—

(a) Solid Phase,  $C_6H_6$ .

Per cent. $C_6H_6$ ...	100	84.6	75.5	64.9	58.6
Temp.....	5.5	0.6	-2.4	-6.0	-8.4

(b) Solid Phase,  $CH_3.COOH$ .

Per cent. $C_6H_6$ ...	54.0	49.7	39.6	29.9	21.4	11.0	3.1	0
Temp.....	-7.4	-6.0	-1.8	2.3	6.0	10.7	14.0	16.3

These ideal freezing-point curves are compared in Table IV with those given for the same acids by dimethyl oxalate and dimethyl succinate, representing esters of strong and weak acids, respectively. The corresponding data for trichloroacetic acid are added for comparison.

TABLE IV.—COMPARATIVE FREEZING-POINT DEPRESSIONS OF ACIDS.

Solvent.	$\Delta T$ with dimethyl succinate.		$\Delta T$ with dimethyl oxalate.		$\Delta T$ with benzene.	
	25 mol %.	50 mol %.	25 mol %.	50 mol %.	25 mol %.	50 mol %.
$CCl_3.COOH$ ...	46.9°	...	27.4°	...	16.5°	36.2°
$CH_2Cl.COOH$ ..	21.9°	54.7°	15.5°	39.4° <sup>3</sup>	9.4°	18.4°
$CH_3.COOH$ ....	16.3°	...	13 $\pm$ 1° <sup>3</sup>	...	11.8°	22.3°

<sup>1</sup> See note 1, page 1730; methyl anisate here assumes its correct position.

<sup>2</sup> Data are those given by Roloff, *Z. physik. Chem.*, 17, 335 (1895); recalculated to molar concentrations.

<sup>3</sup> Values obtained by short extrapolation.

The observed freezing-point lowerings of chloroacetic and acetic acids by the three solutes selected are also shown graphically in Fig. 4. If we compare Curves I, II and V it is evident that benzene gives a normal curve throughout; both esters plainly cause abnormal depression. As before, combination is more extensive with the succinate than with the oxalate. The extent of compound formation with chloroacetic acid is, however, in both cases much less than with the strong acid, trichloroacetic.<sup>1</sup>

Fig. 4.—Freezing-point curves of chloroacetic and acetic acids with esters (solid phase for each curve is indicated at side of diagram).

- I. Dimethyl oxalate—chloroacetic acid.    IV. Dimethyl succinate—acetic acid.  
 II. Dimethyl succinate—chloroacetic acid.    V. Benzene—chloroacetic acid.  
 III. Dimethyl oxalate—acetic acid.

The acetic acid curves are less satisfactorily compared, as the break (change in solid phase) is too near the acetic acid axis. However, Table IV shows that the freezing-point depressions due to 25 mol per cent. of solute assume the same order as with other acids: dimethyl succinate > dimethyl oxalate > benzene. Similarly, from the other (left hand) branch

<sup>1</sup> See Figs. 2 and 3.

of the curves we see that the lowering of the temperature of fusion of dimethyl succinate by acetic acid deviates from the normal "straight line" curve<sup>1</sup> throughout; with dimethyl oxalate a slight "dip" in the curve becomes perceptible only when excess of acetic acid has been added. It is evident, therefore, that even the weak acetic acid combines to some extent with esters. The deviations from the normal curve vary, as before, with the ester considered, but some compound formation is indicated even in such an unfavorable system as acetic acid-dimethyl oxalate.

All acids catalyze ester hydrolysis, the degree of acceleration (for ordinary concentrations) increasing with the strength of the acid. When this is correlated with the fact that all acids form addition compounds with esters, the extent of compound formation also increasing with the strength of the acid, we are led to conclude that the formation of these addition compounds constitutes in reality the first step in ester hydrolysis. Further evidence on this point will be adduced in a subsequent communication.

### 7. Structure of Addition Compounds Isolated.

In these oxonium compounds, either the carbonyl or the hydroxyl oxygen may be quadrivalent, as is shown in Formulas I and II, respectively:

Kendall and Gibbons<sup>1</sup> and Kendall and Carpenter<sup>2</sup> have isolated many compounds of Type I and proved their structure; likewise compounds of alcohols and phenols with acids, illustrating Type II, have been investigated by McIntosh<sup>3</sup> and by Kendall.<sup>4</sup> The definite choice between the two formulas cannot yet be made.<sup>5</sup> It seems that the dimethyl terephthalate compound AB<sub>4</sub> may be a combination of both types.

It is at present premature to attempt to discuss the whole mechanism of ester hydrolysis, *i. e.*, how the oxonium compound, or its positive ion, finally suffers hydrolysis. Several such formulations of the hydrolysis have been put forth, with little experimental support. The authors are now endeavoring to obtain direct experimental evidence on the course of the reaction after the first step, formation of the binary oxonium compound.

<sup>1</sup> THIS JOURNAL, 37, 149 (1915).

<sup>2</sup> *Ibid.*, 36, 2498 (1914).

<sup>3</sup> J. Chem. Soc., 85, 928 (1904).

<sup>4</sup> THIS JOURNAL, 38, 1309 (1916).

<sup>5</sup> Compare Falk and Nelson, *Loc. cit.* Formula II is the one more favored by organic chemists, Stieglitz, Nelson and others having used it, without apparent justification beyond convenience of formulation.

### 8. Summary.

1. The formation of binary compounds of the type ester-acid has been investigated by the freezing-point method. Such compounds have heretofore been assumed to exist, to explain the mechanism of ester hydrolysis as catalyzed by acids, but no conclusive evidence of their presence has been produced. In the present investigation thirteen oxonium compounds of widely differing esters with trichloroacetic acid have been isolated, esters of monobasic acids uniformly yielding equimolecular compounds.

2. Previous papers indicated that oxonium compound formation is in general more evident the more divergent the "acidic strength" of the components employed.<sup>1</sup> Applied to the present case this would demand that combination be most pronounced between *strong* acids and esters of *weak* acids (preferably the alkyl rather than the more "negative" aryl esters). All *three* radicals concerned were varied experimentally as widely as possible and the rule was found to hold throughout the whole range of systems examined.

3. The extent of compound formation varies within wide limits as the above factors are varied. Although decreasing rapidly with decrease in strength of the acid it is still perceptible even with the typical weak acid, acetic acid. We may, therefore, state definitely that *oxonium salt formation is a general phenomenon in systems ester-acid*. These experimental results are in significant agreement with the fact that acceleration of ester hydrolysis is a general property of acids and also decreases with decrease in strength of the acid.

4. The results obtained in this paper are in entire agreement with the "intermediate compound formation" theory as an explanation of acid catalysis of ester hydrolysis. The formation of addition compounds of the type ester-acid as the first step in the mechanism of the reaction may now be regarded as experimentally established.

## THE THERMAL DECOMPOSITION OF SYMMETRICAL DIARYL-HYDRAZINES.<sup>2</sup>

BY JULIUS STIEGLITZ AND HELEN TREDWAY GRAHAM.<sup>3</sup>

Received June 28, 1916.

In the thermal decomposition of hydrazobenzene, azobenzene and aniline are formed according to the equation

<sup>1</sup> Kendall and Gibbons, *THIS JOURNAL*, 37, 149 (1915).

<sup>2</sup> After the completion of the work reported in this paper and after the original

As shown in previous papers<sup>4</sup> from this laboratory, there are several possible courses which the reaction might take to give these products, the study of which seemed to us of special interest from the point of view of the theory of organic chemistry. One of these involves a preliminary dissociation of the hydrazobenzene into phenyl imide and aniline, the azobenzene being the product of a secondary polymerization of the phenyl imide:<sup>5</sup> writing of the same, a report by Wieland on the same subject (*Ber.*, 48, 1098 (1915)) came to hand, in which Wieland arrived at the same conclusion as we had, namely, that one must abandon for symmetrical diaryl hydrazines the theory of Stieglitz and Curme (*Ber.*, 46, 911 (1913)) and *THIS JOURNAL*, 35, 1143 (1913)), which ascribed the monomolecular character of the decomposition of hydrazobenzenes into aryl amines and azobenzenes, involving two molecules of hydrazobenzene, to a measurably slow decomposition of the hydrazobenzene into aryl imide  $\text{PhN} <$  and amine, followed by the fast polymerization of aryl imide to azobenzene. The monomolecular character of the reaction, discovered by Stieglitz and Curme, is not called into question. We should like to point out here that Dr. Curme, in his paper (*THIS JOURNAL*, 35, 1152, footnote 3 (1912)), stated that the critical experiment of the identification of the three possible azo compounds, which the theory would demand for the decomposition of hydrazines  $(\text{Aryl})\text{HN.NH}(\text{Aryl})$  would be made as soon as time permitted. As Dr. Curme left for Europe at that time, the work was continued from this point by Miss Tredway the same autumn and, working with methylhydrazobenzene, we found already, Nov. 10 and Dec. 8, 1913, and with bromohydrazobenzene on Jan. 10, 1914, that only one azobenzene is formed in each case—a result recognized at once as incompatible with the theory of Stieglitz and Curme. In consideration of Curme's reservation, we thought it best to make a much more elaborate investigation of the reaction, with a view to securing results for a positive basis of a revised theory before publishing our findings. We recognize now that an immediate preliminary publication would have been wiser; but we are glad to welcome the fact that in a large measure we are now in essential agreement with the findings of our brilliant German colleague. However, while not denying the possibility of Wieland's new hypothesis (his original one (*Ann.*, 392, 133 (1912)) was disposed of by the discovery by Stieglitz and Curme of the monomolecular character of the reaction), we have developed an alternative hypothesis which we consider of special significance and worthy of more extended investigation, because the reaction under discussion is only a typical case of that large and well-known class of reactions, in which products of an intermediate stage of oxidation are converted under the influence of heat into mixtures of products of lower and higher stages of oxidation. The hypothesis may also be extended to all kinds of oxidation-reduction reactions. In conclusion, we are glad to welcome the fact that Wieland and Reverdy (*Loc. cit.*, p. 1112), by substituting triphenylhydrazine for hydrazobenzene, have actually realized experimentally a thermal decomposition proceeding exactly along the lines of the theory of Stieglitz and Curme, to wit:  $(\text{C}_6\text{H}_5)_2\text{N.NH}(\text{C}_6\text{H}_5) \longrightarrow \text{C}_6\text{H}_5\text{N} + (\text{C}_6\text{H}_5)_2\text{NH}$  (a slow reaction) and  $2\text{C}_6\text{H}_5\text{N} \longrightarrow \text{C}_6\text{H}_5\text{N} : \text{NC}_6\text{H}_5$  (a fast reaction)—showing that the fundamental assumptions of the theory of Stieglitz and Curme were and are essentially sound, in spite of the fact that the dissociation of hydrazobenzene itself follows another course.—J. STIEGLITZ.

<sup>3</sup> The work presented in this article formed the basis of a dissertation submitted by Miss Tredway to the University of Chicago in August, 1915, in part fulfilment of the requirements for the degree of Doctor of Philosophy.

<sup>4</sup> Stieglitz and Curme, *Ber.*, 46, 911 (1913); Curme, *THIS JOURNAL*, 35, 1143 (1913).

<sup>5</sup> See Curme, *Loc. cit.*, in regard to an analogous dissociation into phenyl amide,  $\text{C}_6\text{H}_5\text{NH}$ .

Similar dissociation into unsaturated, reactive radicals had been quite commonly assumed in organic chemistry; the reaction in question seemed to be available for a particularly simple and decisive experimental test of the question by determination of the velocity of the decomposition reaction at a given temperature. A reaction proceeding according to Equations 2 and 3 would be a reaction of the *first order* for the measurably slow reaction (2), the union of phenyl imide radicals according to (3) following with a presumably far greater speed. In such a case, the velocity of the action at a constant temperature should satisfy the equations

$$\frac{dx}{dt} = K_{\text{mono}} (a - x) \quad (4)$$

and

$$K_{\text{mono}} = \frac{1}{t_2 - t_1} \ln \frac{a - x_1}{a - x_2} \quad (5)$$

The symbols have their usual significance.

On the other hand, if the reaction were one of intermolecular oxidation and reduction as expressed in Equation 1, and were due to the high reducing tension of the hydrogen attached to the nitrogen in hydrazobenzene,<sup>1</sup> we would have at a constant temperature a reaction of the *second order*, taking place with a velocity

$$\frac{dx}{dt} = K_{\text{di}} (a - x)^2, \quad (6)$$

from which we find

$$K_{\text{di}} = \frac{1}{t_2 - t_1} \cdot \frac{x_2 - x_1}{(a - x_2)(a - x_1)} \quad (7)$$

In the first paper on this problem, the question was considered whether such an intermolecular oxidation and reduction could not also be a reaction of the first order, involving a preliminary dissociation of hydrazobenzene into azobenzene and hydrogen

followed by the reduction

Inasmuch as the hydrogen had to have a very high reducing tension, and since it could not be considered to have this when it was once liberated as free hydrogen—which does not reduce hydrazobenzene—it was concluded that it could have this high reducing tension only while it was in unstable union with the nitrogen of the hydroazobenzene. Consequently it could be effective only when a second molecule of hydrazo-

<sup>1</sup> Wieland, *Ann.*, 392, 133 (1912); cf. Stieglitz and Curme, *Loc. cit.*

benzene actually met or collided with the first molecule. That would involve dynamically a true bimolecular reaction proceeding according to Equations 6 and 7.

The measurements of the velocities of the decomposition of hydrazobenzene, *p*-methylhydrazobenzene and *p*-hydrazotoluene by Curme showed unquestionably that the velocities followed the monomolecular law expressed in Equations 4 and 5: although some falling off of the constant was observed in the course of the decomposition of 75% of the substance in a given experiment,<sup>1</sup> the *initial velocities* in a range of concentrations from 0.054 to 0.22 molar, were uniformly the same<sup>2</sup>—a relation which, according to the best authorities, is a critical test for the order of a reaction. Furthermore, calculations of  $K_{di}$  according to Equation 7 showed a very wide variation during the course of a single determination, and an enormous variation with a change of the initial concentration.<sup>3</sup> Calculations likewise made very improbable the occurrence of parallel mono- and bimolecular decomposition reactions. The conclusion was therefore drawn that the thermal decomposition of hydrazobenzene is a reaction of the first order, and it was thought that the occurrence of an intermediate dissociation of hydrazobenzene, for instance, into phenyl imide and aniline according to

had been demonstrated. This was the main question the investigation was intended to settle.

Wieland,<sup>4</sup> in discussing these results, proposed the explanation, that the reaction measured was the slow decomposition of the hydrazine into azobenzene and *atomic* hydrogen and that this was followed by the immeasurably fast reduction of another molecule of hydrazobenzene by the liberated hydrogen. One of us had already considered the alternative possibility,<sup>5</sup> as shown above, that azobenzene and *ordinary* hydrogen are formed in a slow reaction and could not reconcile the assumption with the known facts: (1) that hydrogen does not appear to reduce hydrazobenzene under the conditions of the experiment, let alone reduce it with immeasurable speed; and (2) that no indications of the presence of free hydrogen were ever observed in Curme's experiments, carried out in sealed tubes. Both of these facts, it may be remarked here, were confirmed by careful experiments made in the course of the present investigation.

The problem at issue seemed settled therefore in favor of the disso-

<sup>1</sup> For instance, in 0.2 molal solution of hydrazobenzene, at 140.55°,  $10^5 \times K_{mono} = 157, 159, 159, 156, 153, 149, 144$ .

<sup>2</sup> Curme, *Loc. cit.*, tables, pp. 1158-9.

<sup>3</sup> For the 0.2 molal solution,  $10^4 \times K_{di} = 86$ ; and for 0.05,  $10^4 \times K_{di} = 370$ .

<sup>4</sup> *Die Hydrazine*, p. 51 (1913).

<sup>5</sup> Stieglitz and Curme, *Ber.*, 46, 914 (1913).

ciation theory (Equations 2 and 3), by the unquestioned order (monomolecular) of the reaction and by the experimental fact that a reduction of hydrazobenzene required a higher reducing tension than that possessed by free hydrogen.<sup>1</sup> But the whole problem was opened again for further investigation by the following observations: in the decomposition of hydrazines with two different aryl groups—such as *p*-methyl hydrazobenzene,  $C_6H_5NH.NHC_6H_4CH_3$ —a preliminary dissociation into phenyl imide radicals and anilines should yield ultimately three azo compounds,  $C_6H_5N : NC_6H_5$ ,  $C_6H_5N : NC_6H_4CH_3$  and  $CH_3C_6H_4N : NC_6H_4CH_3$ , and two anilines,  $CH_3C_6H_4NH_2$  and  $C_6H_5NH_2$ , presumably in unequal proportions, since the decompositions

and

would almost certainly not be equally favored. As a matter of fact, Dr. Curme's experimental data<sup>2</sup> showed that in the decomposition of *p*-methylhydrazobenzene, just about twice as much toluidine is formed as aniline. A reduction by way of Equations 8 and 9 would demand equal molar proportions of the two anilines. This result therefore agreed perfectly with the main conclusion drawn in favor of the dissociation theory. It was planned<sup>3</sup> to confirm the conclusion by identifying the three azo compounds which should be formed under these conditions, but Dr. Curme's departure for Europe necessitated the postponement of this examination. It was at this point that the present investigation was taken up, with the unexpected but convincing result that in the thermal decomposition of *p*-methyl-hydrazobenzene and of *p*-bromohydrazobenzene, only a *single azo compound* is produced—the one corresponding to the hydrazo compound used. Thus from methylhydrazobenzene,  $C_6H_5NH.NHC_6H_4CH_3$ , only methylazobenzene,  $C_6H_5N : NC_6H_4CH_3$ , is obtained; from *p*-bromohydrazobenzene,  $C_6H_5NH.NHC_6H_4Br$ , only bromoazobenzene,  $C_6H_5N : NC_6H_4Br$ , is produced.

This conclusion was amply confirmed by careful determinations of the proportions of anilines,  $C_6H_5NH_2$  and  $XC_6H_4NH_2$ , formed in the thermal decomposition: by the use of more elaborate and accurate methods than that used by Curme, it was found that the proportion is 1 : 1, as required for a direct reduction of a molecule of the hydrazobenzene,  $XC_6H_4NH.NHC_6H_5$ .

<sup>1</sup> Since then the actual existence and great reactivity of *atomic* hydrogen as compared with ordinary hydrogen has been demonstrated by Langmuir (THIS JOURNAL, 36, 1708 (1914) and 37, 417 (1915)).

<sup>2</sup> Curme, THIS JOURNAL, 35, 1171 (1913).

<sup>3</sup> Curme, *Loc. cit.*, p. 1152, footnote 3.

These results are irreconcilable<sup>1</sup> with the theory of a preliminary dissociation into phenyl imide radicals,<sup>2</sup> as expressed in Equations 3 and 4, and thus the whole problem of the mechanism of the reaction was reopened.

The following facts were next established:

(1) For concentrations ranging from 0.2 to 0.05 molar, the reaction is actually one of the first order, as found by Curme. The main experimental part of Curme's work was thus fully confirmed.

(2) In very dilute solutions (0.01 to 0.005 molar), the reaction is no longer clearly one of the first order; in individual experiments fairly good constants for a second order reaction (Equation 7) are obtained, but the constants for different concentrations do not agree at all with one another. The order of the reaction, therefore, in very dilute solutions is uncertain and probably neither wholly of the first nor of the second order.

(3) In a sealed tube charged with an alcoholic solution of an excess (relative to the hydrogen) of bromohydrazobenzene in an atmosphere of hydrogen, and heated for two hours at 145°, the temperature at which the decomposition reaction was studied, no absorption of hydrogen of any moment was discernible. There is, therefore, no direct reduction with immeasurable speed. The action

must therefore be considered excluded in the theory of the thermal decomposition of arylhydrazines.

(4) In extremely dilute solutions (0.01 molar), a little permanent gas is formed, but it fails to respond to the tests for hydrogen, made both with palladium and oxygen, and with oxygen in an explosion pipet<sup>3</sup> (see the experimental part). The absence of hydrogen, taken in conjunction with its failure to react when used with hydrazobenzene, shows that ordinary hydrogen cannot be considered an intermediate product in the thermal decomposition of the arylhydrazines.

(5) The molecular weight of *p*-bromohydrazobenzene was determined in boiling absolute alcohol solution and found to be that of the simple

<sup>1</sup> See Wieland, *Ber.*, 48, 1098 (1915) and the introductory note to this article.

<sup>2</sup> A dissociation of this type, however, was found by Wieland and Reverdy (*Ber.*, 48, 1112 (1915)) to occur in the case of triphenylhydrazine,  $(\text{C}_6\text{H}_5)_3\text{N.NHC}_6\text{H}_5$ .

<sup>3</sup> As the exact nature of this permanent gas, especially as to the question of its containing hydrogen, seemed of particular theoretical significance (see below), Mr. E. N. Roberts in the autumn of 1915 kindly undertook its re-examination. He confirmed the finding of Mrs. Graham that it contains no hydrogen and further established the fact that aside from the presence of the small amount of oxygen and nitrogen left as air in the tube sealed under 18 mm. pressure, a very large proportion of nitrogen is present (at least 75% of the total volume in excess of the air nitrogen). The nitrogen was converted into ammonia by sparking it with hydrogen over sulfuric acid, and the ammonia determined both by titration and by nesslerizing.—J. S.

molecule,  $\text{C}_6\text{H}_5\text{NH.NHC}_6\text{H}_4\text{Br}$ . The simple explanation<sup>1</sup> of a reaction of the first order between two molecules of hydrazobenzene as being due to a dimolecular form is thus excluded. The monomolecular form being found at  $78^\circ$ , there should be no polymerization at  $140^\circ$  and  $150^\circ$ , the temperatures at which the experiments were conducted. The possibility that in a reversible reaction

small quantities of a dimolecular form are present and decomposed, would clearly lead to "constants" varying with the concentration,<sup>2</sup> and this possibility is therefore also excluded.

We are thus called upon to reconcile the fact that the thermal decomposition of hydrazines in solutions of moderate concentration (0.05 to 0.2 molar) is certainly one of the first order indicating a decomposition of only a *single molecule*—with the fact that no ordinary decomposition product of the single molecule, namely neither phenyl imide,<sup>3</sup>  $\text{C}_6\text{H}_5\text{N}$ ·, nor hydrogen,  $\text{H}_2$ , can be formed as an intermediate product, and with the further fact that a *second* molecule of the hydrazobenzene is nevertheless reduced at great speed in some way as the result of the decomposition of the first molecule. We have, in a word, a dimolecular reaction of the first order. Two possible explanations of this set of facts suggest themselves as the most plausible ones. The first of these<sup>4</sup> is that the monomolecular reaction, whose velocity we have measured, is a decomposition of the hydrazobenzenes into azobenzene and *atomic* hydrogen. Langmuir<sup>5</sup> has recently proved that atomic hydrogen is capable of existence, and is *vastly more reactive* than ordinary or molecular hydrogen. The high reducing tension of the hydrogen which, as we have seen, is neces-

<sup>1</sup> This explanation was apparently not considered by Wieland.

<sup>2</sup> If  $C_{di}$  and  $C_{mon}$  represent the respective concentrations of the dimolecular and monomolecular forms at any moment of equilibrium, we have  $C_{di} = K_{eq} \times C_{mon}^2$ . For a reaction, which might be of the first order for the polymerized form,

$$\frac{dx}{dt} = K_{vel} \times C_{di}$$

we would have by substitution

$$\frac{dx}{dt} = K_{vel} \times K_{eq} \times C_{mon}^2.$$

Consequently, if the main amount of hydrazobenzene is present in the monomolecular form—as has been proved by our experimental work—the order of the reaction would still appear as of the second order, even if the small amounts of the dimolecular form were the reacting component. Only if  $K_{eq}$  were quite large and by far the greater part of the substance were present in the associated form, would the reaction appear as one of the first order, the dependence of the associated molecules on the nonassociated ones involving only a small error, which could be within the limits of the experimental error.

<sup>3</sup> Or phenyl amide,  $\text{C}_6\text{H}_5\text{NH—}$ .

<sup>5</sup> THIS JOURNAL, 36, 1708 (1914); 37, 417 (1915).

sary for the reduction of a second molecule of hydrazobenzene may reside and be maintained therefore not only in hydrazobenzene itself, but also in atomic hydrogen sufficiently long for the latter to reach and reduce the second molecule of hydrazobenzene. We would have,

and

This is an important modification of a possible monomolecular reaction given by Stieglitz and Curme in their first paper, in which the formation of ordinary hydrogen,  $\text{H}_2$ , was considered.<sup>1</sup> The present view was first advanced by Wieland.<sup>2</sup> It would overcome the objections to the original interpretation raised by Stieglitz and Curme—objections which without this modification would still exist. The modification consists in the assumption that the hydrogen is *atomic* hydrogen of a proved much higher degree of activity than that possessed by ordinary hydrogen.

Now, while we consider this explanation of the thermal decomposition of hydrazobenzenes a possible one, there are certain objections to it, which should be pointed out. In the first place, it should require *time* for the atomic hydrogen to *diffuse* through the solution to the second molecule of hydrazobenzene and reduce it; and instantaneous reduction is therefore out of the question. In the second place, in this process of diffusion, two separate atoms of hydrogen would have to move toward the same hydrazobenzene molecule—the *directing cause for which coincidence it would be hard to find*. And, finally, in this irregular diffusion it is certainly to be expected that a measurable part at least of the atomic hydrogen would, by a collision of the atoms, form ordinary *unreactive* hydrogen, especially in view of the original *proximity* of the two atoms, in leaving the mother hydrazone molecule, compared with the distance to a further molecule of hydrazine. As emphasized above, in solutions of moderate concentration no indications of the formation of any permanent gas at all were obtained; and in dilute solutions (0.01 molar), where a little permanent gas was obtained, it failed to respond to any test for hydrogen.<sup>3</sup> These considerations, and especially the last one, it seems to us, make the alternative hypothesis which we will now present, more likely to be the correct interpretation of the reaction.

This interpretation, based on the electron theory of valence, has interested us in particular because one of us has long suspected the possibility of oxidation and reduction in solution occurring by a transfer of electrons from molecule to molecule, *without the necessity of a collision* (or approach to within molecular distances) *between the respective mole-*

<sup>1</sup> *Loc. cit.*

<sup>2</sup> *Die Hydrazine*, p. 51 (1913).

<sup>3</sup> See footnote 3, p. 1741.

rules. The present case is, we believe, the first instance where evidence of such an action has been recognized in solution in a simple thermal reaction.<sup>1</sup> According to the electron theory of valence, hydrazobenzene, in common with hydrazines in general, has the structure<sup>2</sup>

When it forms azobenzene and aniline, two electrons are discharged by the nitrogen of the one (reducing or oxidized) molecule, producing azobenzene,  $(\text{C}_6\text{H}_5^+) - \text{N}^+ = \text{N}^- (+\text{C}_6\text{H}_5)$  or  $(\text{C}_6\text{H}_5^+) - \text{N}^+ = \text{N}^- (+\text{C}_6\text{H}_5)$ , and releasing, as a consequence, two positively charged hydrogen atoms or ions. On the other hand, the nitrogen of the second (reduced) molecule absorbs two electrons to form aniline, in which the nitrogen is unquestionably wholly negative,<sup>3</sup>  $(\text{C}_6\text{H}_5^+) \text{N} \equiv (\text{H}^+)_3$ , as in ammonia; the absorption of two electrons must disrupt the union of the nitrogen atoms in this second molecule of hydrazobenzene, and give to the two negative radicals or ions  $\text{C}_6\text{H}_5\text{NH}^-$  formed the power to absorb two positively charged hydrogen atoms or ions (see the equations below). Now, it is easily conceivable that the two electrons discharged by the reducing (oxidized) molecule should pass with very great speed through the solution to the positive valence of the nitrogen in the second molecule; electrons have, of course, at a given temperature, normally, velocities perhaps forty times as great as hydrogen atoms, at the same temperature; and moreover, on account of their volume being, let us say, 1800 times as small as that of the hydrogen atom, they would meet with an enormously smaller resistance in a liquid medium than hydrogen atoms would. Electrons are known indeed to pass even through the interstices of atoms. The two electrons in question could therefore reach the second molecule of hydrazobenzene with a sufficient speed to be negligible; charging the nitrogen of this molecule wholly negatively, they would sunder the molecule, and the negative phenyl amide radicals would unite with two positive hydrogen atoms, derived either from the medium surrounding them or from the oxidized hydrazobenzene molecule. The *actual* reduction<sup>4</sup> would consist in the absorption of the two electrons—the union with the

<sup>1</sup> Bodenstein (*Z. physik Chem.*, 85, 330 (1913)) has treated photochemical effects from a similar point of view. The work of Lind (*J. Phys. Chem.*, 16, 494 (1912)) on the influence of radioactive rays on the oxidation of hydrogen by halogens and the work of H. S. Taylor (*THIS JOURNAL*, 37, 24 (1915)) are also suggestive in this connection. C. A. Kraus (*THIS JOURNAL*, 36, 864 (1914)) proved the independent existence of electrons in the colored solutions of the alkali metals in ammonia.

<sup>2</sup> Only the essential charges are indicated.

<sup>3</sup> In regard to its first three valences.

<sup>4</sup> A well-known conception. See, for instance, Stieglitz, "Qualitative Analysis," Vol. I, pp. 251-298 (1911).

positive hydrogen is a simple ionic union of anions and cations. We can express this interpretation<sup>1</sup> in the following equations:

which would be a slow decomposition reaction, whose velocity is measured;

and

which would be exceedingly fast reactions, following the first slow decomposition reaction.

It should be observed that such an action would produce local potential differences in small elements of space; for instance, if  $\text{H}^+$  were liberated at the end of one such element and  $-\text{OC}_2\text{H}_5$  at the other end when  $\text{H}^+$ , derived from the solvent, is absorbed by the second molecule of hydrazobenzene, we would have for a small time interval, a local potential difference. The same situation would result if the positive hydrogen finally absorbed were the  $\text{H}^+$  given off by the first (oxidized) molecule of hydrazobenzene; since the electrons are considered to reach the second (reduced) hydrazobenzene molecule with far greater speed than the  $\text{H}^+$ , we would have local polarization in which in the small element of space, the hydrogen would be positive, the phenyl amide,  $\text{C}_6\text{H}_5\text{HN}^-$ , would be negative. Such potential differences would be distributed exceedingly irregularly, that is, in all directions, and would neutralize each other with greatest rapidity by irregularly distributed currents or combinations of ions in the elements of space. It is evident, further, that such a transfer of electrons would become much more difficult in solutions of extreme dilution,

<sup>1</sup> This electronic interpretation lends itself equally well to the decomposition of triphenylhydrazine into diphenylamine and azobenzene by way of an intermediate dissociation into diphenylamine and the phenyl imide radical  $\text{C}_6\text{H}_5\text{N}$ , as postulated by the theory of Stieglitz and Curme and realized by Wieland and Reverdy (*Loc. cit.*). In this case the primary action is one of *intramolecular* oxidation-reduction, instead of an intermolecular one as for hydrazobenzene.

is the initial action, two electrons, designated by heavy type for the corresponding negative charges, passing from the phenyl amide nitrogen atom to the diphenylamide nitrogen atom to make the latter wholly negative. As a result, the union between the nitrogen atoms is rendered and  $\text{H}^+$  is also lost by the one nitrogen atom, and either transferred directly to the ion  $(\text{C}_6\text{H}_5)_2\text{N}^-$  or it takes the place of a hydrogen ion absorbed by the latter from the solution. The union of two phenylimide radicals to form azobenzene completes the action.

and that as a result the simple order of the action could be changed. This might account for the change in the order of the reaction, when we use very dilute solutions (0.01 molar), from a simple monomolecular one to an indefinite one. In particular, we would recall in this connection the fact that Bodenstein found that the combination of chlorine with hydrogen under the influence of alpha particles is *independent of the concentration of the reducing hydrogen down to a certain limiting concentration of hydrogen*. In the instance we are discussing, we may say that the velocity of the action seems to be independent of the concentration of the molecules of hydrazobenzene down to a certain limiting concentration—which makes the action essentially monomolecular down to that limit.

We recognize the hypothetical character of this theory,<sup>1</sup> but are proposing it not only as an attractive working hypothesis for the case under consideration, but as opening up a problem in the field of the dynamics of oxidation and reduction that has long interested one of us. The theory seems to us to have advantages over the first theory involving atomic hydrogen in that it gives a reasonable explanation of an almost instantaneous reduction of the second molecule of hydrazobenzene, unhampered by the necessity of instantaneous diffusion of such large atoms as hydrogen through an obstructing liquid, in that it gives a reasonable explana-

<sup>1</sup> The alternative hypothesis that *atomic* hydrogen is first released by the reducing molecule of hydrazobenzene (Wieland's later theory), when analyzed from the electronic point of view, simply signifies that the two electrons discharged by the nitrogen of this reducing molecule of hydrazobenzene are *first absorbed* by the two positive hydrogen atoms held by the nitrogen, instead of passing directly, as free electrons, from one molecule of hydrazobenzene to the other:

The two atoms of hydrogen would then pass through the solution (without any evident directive force) to the second molecule of hydrazobenzene and would there lose the two electrons to a nitrogen atom of the latter and be absorbed as positive hydrogen atoms. The difference between the two theories is then essentially the question whether we must assume the formation of an *intermediate product*, atomic hydrogen, as the *carrier of the electrons*, or whether we must assume the direct transfer of the electrons. Since the independent existence of electrons as atoms and molecules has been amply demonstrated, it seems to us the question raised is not only a reasonable one, but indeed one of fundamental interest. Further investigation of the actual relations seems, therefore, highly desirable; this will include among other methods of attack, attempts to detect any possible (perhaps momentary) conductivity in the solutions in which the decomposition is proceeding, as well as further investigation of the gas formed in extreme dilution. In conclusion, it should be said that this whole problem, *mutatis mutandis*, will be investigated in connection with other well-known cases of oxidation-reduction, especially also of compounds of an intermediate stage of oxidation, both in organic and especially also in well-known inorganic reactions.—J. S.

tion of the fact that no free hydrogen has been observed in the study of the decomposition; and in introducing a directive force (due to the positive charge on the nitrogen of the oxidizing molecule of hydrazobenzene) for the migration of two particles (electrons), to the same molecule.<sup>1</sup>

### Experimental Part.<sup>2</sup>

BY HELEN TREDWAY GRAHAM.

**1. Preparation and Analysis of the Hydrazo Compounds.**—The three hydrazo compounds used in this investigation—*p*-methylhydrazobenzene, *p*-bromohydrazobenzene, and 2,4-dichlorohydrazobenzene—were prepared by reduction of the corresponding azo compound with zinc dust in alkaline alcoholic solution. The azo compounds themselves were made by the method of Mills<sup>3</sup> from nitrosobenzene and the substituted aniline. The *p*-methylhydrazobenzene was identical in every respect with that described and used by Curme.<sup>4</sup> In preparing the halogen hydrazo compounds, a pink impurity was noticed, the nature of which was not investigated, but which could be removed only by several recrystallizations of the azo compounds before reduction.

***p*-Bromohydrazobenzene**,  $p\text{-BrC}_6\text{H}_4\text{NH.NHC}_6\text{H}_5$ , made by reduction of pure *p*-bromoazobenzene (m. p.  $89^\circ$ ), and twice recrystallized from alcohol containing a few grams of zinc dust and several drops of concentrated ammonium hydroxide solution, was obtained as shiny, white plates

<sup>1</sup> A third interpretation of this characteristic monomolecular oxidation and reduction reaction, involving ultimately two molecules of hydrazobenzene, is found in a combination of the two theories that have been presented. That is, the first, measurably slow reaction, may consist in the loss of two electrons by the reducing molecule of hydrazobenzene to a *single* one of the hydrogen atoms  $\text{H}^+$  which it loses—making it a *negative* hydrogen atom  $\text{H}^-$ , of even greater reducing power than atomic hydrogen. Negative hydrogen has been assumed by Fry (*Z. physik. Chem.*, **76**, 385 (1911) and later papers in *THIS JOURNAL*) to exist in certain organic compounds, and it certainly exists and shows its tremendous reducing power in the salts of hydrogen, such as sodium, potassium or calcium hydrides. The detailed application of the idea of the formation of negative hydrogen to the interpretation of the reaction we are investigating is not necessary, as it is indicated sufficiently clearly by our previous discussion. It would, it seems to us, have the advantage over Wieland's theory of the formation of atomic hydrogen, that we would have only a single atom of hydrogen moving to the second molecule of hydrazobenzene to reduce it, which would be guided moreover by the electrical attraction between its negative charge and the positive charge on the nitrogen. It should, however, lead still more easily and almost inevitably to the formation of some ordinary hydrogen  $\text{H}_2$  by collision with a hydrogen ion and for this reason we believe our theory of a direct transfer of electrons is most likely to be found to be the correct interpretation of the reaction.

<sup>2</sup> I take pleasure in using this opportunity of thanking my young collaborator, Mrs. Graham, to whose skill and perseverance the experimental part of this investigation is wholly due.—J. S.

<sup>3</sup> Mills, *J. Chem. Soc.*, **67**, 929 (1895).

<sup>4</sup> Curme, *Loc. cit.*, p. 1166.

melting at  $101-101.5^{\circ}$ .<sup>1</sup> Once dry, *p*-bromohydrazobenzene is very stable at ordinary temperatures; a sample was left exposed to the air of the laboratory for two weeks before it showed the slightest discoloration or change in melting point. For the determination of its purity the substance was oxidized in absolute alcohol with 0.1 *N* iodine solution. The solutions were made up and the analysis carried out exactly as described by Curme for hydrazobenzene,<sup>2</sup> except that we found it necessary to allow the iodine to act on the bromohydrazobenzene for an hour instead of ten minutes before acidifying the mixture and titrating the excess of iodine with thiosulfate. A weighed amount of 0.1 *N* iodine solution was first introduced into a glass-stoppered Erlenmeyer flask, and to it was added alcoholic aniline solution (approximately 0.1 *N*), sufficient to give an excess of 2-3 cc. over the amount required to neutralize the hydriodic acid to be formed in the subsequent oxidation. The weighed sample of *p*-bromohydrazobenzene was then dissolved in absolute alcohol and transferred with rinsing to the flask containing the iodine. The whole mixture was allowed to stand one hour, was then acidified with 10 cc. 6 *N*-sulfuric acid, and diluted to approximately 500 cc. with water. Bright yellow crystals of bromoazobenzene were thus precipitated. Standard 0.1 *N* thiosulfate solution was then run in until the fading of the brown color of the iodine indicated the approach of the end point, and starch indicator (10 cc.) was added, producing a greenish black discoloration. The thiosulfate solution was then introduced drop by drop until the bright yellow color of the azo compound was just restored. Blank experiments showed that the factor of the iodine solution was not materially affected by the presence of the aniline solution or by evaporation during the hour it was allowed to stand.

0.2901 and 0.2092 g. subst. required 15.24 and 15.92 g. 0.1 *N* iodine. Theory: 15.23 and 15.90 g.

**2,4-Dichloroazobenzene**,  $\text{Cl}_2\text{C}_6\text{H}_3\text{N}:\text{NC}_6\text{H}_5$ .—The preparation and purification of this substance offers much more difficulty than that of the other azo compounds employed. 2,4-Dichloroaniline was dissolved in glacial acetic acid, and nitrosobenzene added to the warm solution, which was refluxed for an hour. Cooling precipitated a black crystalline mass, which was collected on a filter, washed with 50% alcohol, dried thoroughly by suction, and extracted with ligroin (b. p.  $30-50^{\circ}$ ). The ligroin solution was filtered from black insoluble particles and evaporated to dry-

<sup>1</sup> Janovsky and Erb (*Ber.*, 20, 364 (1887)), who reduced *p*-bromoazobenzene with ammonium hydrosulfide in alcoholic solution, give the melting point of the hydrazo product as  $115^{\circ}$ ; this method of reduction was tried and gave a product with the melting point,  $101-101.5^{\circ}$ , given above. Janovsky and Erb also give an incorrect melting point,  $85^{\circ}$ , for *p*-bromoazobenzene (*Ber.*, 19, 2155 (1886)).

<sup>2</sup> *Loc. cit.*, p. 1155.

ness. The product was then recrystallized from 95% alcohol several times, until it had a constant melting point of  $105^{\circ}$ , and a brilliant orange color. The best yield of crude dichloroazobenzene obtained was 45%, and recrystallization to the required purity reduces the yield to 10–20%. Addition of water to the acetic acid solution filtered from the black mass, and to the wash liquid, precipitated fine light green needles which were very soluble in alcohol, melted at  $137^{\circ}$ , and on recrystallization from dilute alcohol, melted at  $139^{\circ}$ . Mixed with acetodichloroanilide (white rhombohedrous melting at  $143^{\circ}$ ), they melted at  $100^{\circ}$ , which proved that they were not acetodichloroanilide. No further attempt was made to determine the nature of the green product.

**2,4-Dichlorohydrazobenzene**,  $\text{Cl}_2\text{C}_6\text{H}_3\text{NH.NHC}_6\text{H}_5$ .—The azo compound can be reduced almost quantitatively to 2,4-dichlorohydrazobenzene by treatment with zinc dust in ammoniacal alcoholic solution, filtration from the zinc dust in an atmosphere of carbon dioxide, and precipitation of the hydrazo compound with warm, air-free water. The oil which first separates out, crystallizes on cooling. The product so obtained, even after several recrystallizations, invariably contained a trace of pink impurity similar to the one observed occasionally in the preparation of *p*-bromohydrazobenzene. As dichlorohydrazobenzene very easily becomes contaminated with some dichloroazobenzene by oxidation, material which was pinkish yellow in color, melted at  $73.5\text{--}74^{\circ}$ , and analyzed 95–96% pure, was used in the velocity experiments. A very small amount of pure dichlorohydrazobenzene was obtained by reduction of the purest dichloroazobenzene, the pink impurity being removed from the hydrazo compound by fractional precipitation with warm water. The slight amount of impurity present was entirely precipitated by a quantity of water insufficient to precipitate all the hydrazo compound; and as the solution was carefully protected from the air, the addition of more water to the filtrate precipitated almost colorless plates of dichlorohydrazobenzene, which melted at  $74.5^{\circ}$ , and analyzed 99.7% pure. Dichlorohydrazobenzene is so easily oxidized that it was found necessary to allow only ten minutes for the action of the iodine. In the analyses of this substance, no aniline was used to neutralize the hydriodic acid formed; but instead, the oxidation was carried out in the presence of sufficient acid ammonium carbonate to neutralize the acid formed in the oxidation, and in the presence of carbonic acid, liberated by the addition of acid ammonium carbonate to a measured quantity of hydrochloric acid. This method of neutralization was developed in connection with the work on the ratio of the two amines formed in the decomposition of *p*-bromohydrazobenzene and was found quite as satisfactory as the use of aniline.

0.1395 g. subst. required 10.99 g. 0.1 *N* iodine. Calculated, 11.02 g.

**2. Thermal Decomposition Products of Asymmetrical Hydrazobenzenes.**<sup>1</sup>—In order to find out whether a mixture of azobenzene and its mono- and di-substituted derivatives could be separated into its components on the basis of their different solubilities in alcohol, 0.5 g. azobenzene, 0.5 g. *p*-methylazobenzene, and 0.5 g. *p*-azotoluene were thoroughly powdered and mixed, and the mixture extracted with 15 cc. 95% alcohol at 0°. The yellow crystals obtained by the evaporation of the alcohol melted at 46–47°, while the part which did not dissolve in the alcohol melted at 59–61°. A second extraction with 10 cc. alcohol at 0° left a residue which melted at 117–137°, while evaporation of the alcohol yielded crystals melting at 47–48°. The melting points of azobenzene, *p*-methylazobenzene, and *p*-azotoluene are 69°, 70° and 144°, respectively. It is therefore clear that, even without completing the separation, fractionation with alcohol at 0° would very easily distinguish between a mixture of the three azo compounds and *p*-methylazobenzene alone.

*p*-Methylhydrazobenzene (1.7 g. in 10 cc. absolute alcohol) was then heated for fifteen hours at 125°, in tubes which had been sealed off at a pressure of 15 mm. The solution was allowed to evaporate in the air, after dilute hydrochloric acid had been added to acid reaction with litmus, for the purpose of neutralizing the amines formed by the decomposition. Orange-colored crystals appeared, which were transferred to a filter with water, and washed with water till they were free from acid. When dry, they melted at 70°. They were extracted three times with 10 cc. alcohol at 0°, and the residues and the crystals from evaporation of the alcohol melted uniformly at 70°, alone and when mixed with a known sample of *p*-methylazobenzene. An independent experiment showed that under the conditions used, *p*-azotoluene would not have been acted upon by the aniline present, the reaction

being thus excluded. Therefore, no *p*-azotoluene was formed in the decomposition of *p*-methylhydrazobenzene.<sup>2</sup> Exactly the same results were obtained when the products of the decomposition in 0.2 molal solution were examined.

The experiment was then repeated with 2.8 g. *p*-bromohydrazobenzene in 10 cc. absolute alcohol and perfectly analogous results were obtained.<sup>3</sup> Fractionation with alcohol had no effect on the melting point of the product, the various fractions melted uniformly at 89°, the melting point of

<sup>1</sup> See the theoretical part.

<sup>2</sup> This result was obtained Nov. 10 and Dec. 8, 1913 (see the introductory footnote to this article).

<sup>3</sup> Jan. 10, 1914.

*p*-bromoazobenzene, whether tested alone or mixed with a known sample of *p*-bromoazobenzene.

Dichlorohydrazobenzene (2 g., 95–96% pure), treated in the same way, yielded on cooling a mass of bright orange needles, which were separated by filtration from the red alcoholic solution, and extracted three times with alcohol. The melting point of the needles was 100°, and this was raised to 103° by the mixing of the crystals with pure dichloroazobenzene (m. p. 105°). The residues from the extractions melted at 105°, as did the crystals obtained by evaporation of the alcoholic filtrates from the last two extractions. Evaporation of the acidified alcoholic solution, and of the alcohol used in the first extraction, gave orange-colored crystals melting below 100°. In no case did admixture of dichloroazobenzene lower the melting point still further, and the impurities which caused the low melting point could hardly have included tetrachloroazobenzene (m. p. 161°), which is but little soluble in alcohol.<sup>1</sup> The more insoluble fractions always had the melting point of 2,4-dichloroazobenzene.

In the determination of the ratio of the two amines formed in the decomposition, the method of precipitation of their hydrochlorides<sup>2</sup> was used, with subsequent bromination with 0.1 *N* potassium bromate solution.<sup>3</sup> Of the three hydrazo compounds studied, *p*-bromohydrazobenzene was most suitable for this purpose, since the two amines from *p*-methylhydrazobenzene have nearly the same molecular weight, and since dichloroaniline is only very slightly basic.<sup>4</sup> A 0.2 molal solution (10 cc.) of bromohydrazobenzene in alcohol was heated at 145° in evacuated tubes for 12 hours; after the tubes had been cooled, their contents were introduced into a distilling flask containing 15 cc. 0.1 *N* HCl, 0.3 g. acid ammonium carbonate, and an excess of 0.1 *N* iodine solution. The oxidation of the undecomposed hydrazo compound by the iodine was thus carried out in the presence of carbonic acid and ammonium acid carbonate, *i. e.*, in a very slightly alkaline medium, and rearrangement of the hydrazo compound under the influence of acid therefore avoided. The mixture was allowed to stand for ten minutes before it was acidified with 20 cc. of 6 *N* sulfuric acid. It was then distilled with steam until the azo compound had all passed over, and the further distillate was colorless. Sodium hydroxide (20 cc. of a 10 *N* solution) was added to the mixture in the distilling flask, and 100 cc. of the liquid were distilled from the alkaline solution into dilute hydrochloric acid. This solution of the amine hydrochlorides was evaporated down to about 25 cc. by dry air drawn through

<sup>3</sup> Curme, *Loc. cit.*, p. 1162. Cf. also p. 1169 for the less direct method there described in the study of the proportion of the two amines from *p*-methylhydrazobenzene, and the results obtained.

<sup>4</sup> Witt, *Ber.*, 7, 1602 (1874).

it at reduced pressure at  $55^{\circ}$ ; it was then transferred to a separatory funnel, made alkaline with 33% potassium hydroxide solution, and extracted with alcohol-free chloroform until the aqueous layer gave no color with chloride of lime.<sup>1</sup> The chloroform solution was filtered through a cotton plug in the stem of a funnel into a weighed beaker; sodium-dried ether (2 cc.), saturated with hydrogen chloride gas, was added to the chloroform to convert the amines into the hydrochlorides, and partly precipitated them as such; the liquid was evaporated by dry air drawn over the beaker. The hydrochlorides were then dried to constant weight in vacuum over calcium chloride, extracted with 2-3 cc. ligroin to remove any organic impurities, and again weighed to constant weight. The product thus obtained was almost colorless, and was analyzed by bromination as follows: A weighed portion of the mixed hydrochlorides was dissolved in a small amount of water in an Erlenmeyer flask, and 10 cc. 10% potassium bromide solution added to the solution. A definite amount of standard 0.1 *N* potassium bromate was run in from a buret, the flask closed by means of a paraffined cork holding a calcium chloride tube containing glass beads moistened with potassium iodide solution, and the mixture kept in a water bath at  $50^{\circ}$  for fifteen minutes. White tribromoaniline was precipitated out, and the solution was colored yellow by the excess of free bromine. Potassium iodide (10 cc. of a 10% solution) was rinsed through the glass beads, the mixture was cooled, and the end point determined with 0.1 *N* thiosulfate solution and starch indicator. Blank experiments with known amounts of aniline, bromoaniline, bromoazobenzene, and bromohydrazobenzene, corresponding to the amounts present in 10 cc. of a 0.2 molal solution of bromohydrazobenzene after 12 hours' heating, showed that the ratio of amines could be determined by this method with an accuracy of 0.4%.<sup>2</sup> But as there are undoubt-

<sup>1</sup> Ten drops of half-saturated chloride of lime solution will produce a distinct brown color in 3 cc. of a slightly alkaline solution of *p*-bromoaniline containing as little as 2 milligrams of the amine. The ordinary test for aniline can therefore be used to test for both amines in question.

<sup>2</sup> If we put:  $x$  = millimols of aniline hydrochloride used,  
 $y$  = millimols of bromoaniline hydrochloride used,  
 $g$  = weight of mixed hydrochlorides used,  
 $c$  = volume, in cc., of 0.1 *N* bromate used,

then we have:

$$\begin{aligned} 0.1295 x + 0.2085 y &= g \\ 60 x + 40 y &= c \end{aligned}$$

(Cf. Curme, *Loc. cit.*)

A mixture of 0.0728 g. aniline and 0.1449 g. bromoaniline with 0.15 g. bromohydrazobenzene and 0.40 g. bromoazobenzene was run through the entire process, beginning with the oxidation of the hydrazo compound by 0.1 *N* iodine solution. 0.0613 g. of the mixed hydrochlorides required 17.90 cc. 0.1 *N*  $\text{KBrO}_3$ . These analytical data give 48.49 molar % aniline, while there was actually present in the original mixture of amines, 48.14 % aniline.

edly present in the decomposed hydrazo solution, products of benzidine or similar rearrangements which are somewhat volatile with steam from basic but not from acid solution, the error in an actual determination may be larger. In any case, however, it is well within the necessary limit of accuracy. The following results were obtained in two experiments carried out as described:

Gram amine hydrochlorides.	Cc. 0.1 <i>N</i> KBrO <sub>3</sub> .	Molar percentages.	
		Aniline.	Bromoaniline.
0.0627	18.58	50.2	49.8
0.0673	19.63	48.4	51.6

The above experiments establish the fact that there is only one azo compound, the asymmetrical one, found in the thermal decomposition products of asymmetrical hydrazobenzenes; and the further fact that the two amines are found in equimolecular proportions. The interpretation of the reaction involving the formation of phenyl imide radicals must therefore be incorrect.<sup>1</sup>

**3. The Velocity of Decomposition of *p*-Bromohydrazobenzene and 2,4-Dichlorohydrazobenzene.**—In order to justify the assumption that *p*-bromo- and 2,4-dichlorohydrazobenzene would resemble the hydrazo compounds studied by Curme, and give velocity constants according to the law for a monomolecular reaction (see Equation 5), determinations of the velocity of decomposition were carried out with *p*-bromohydrazobenzene and dichlorohydrazobenzene in alcoholic solution. Curme's apparatus and methods<sup>2</sup> were used, the tubes containing the solution being sealed off in a freezing mixture at a pressure of 10–20 mm. The whole number of tubes was then heated to 70–80° in a small oil bath and plunged simultaneously into the thermostat at 145°. On removal from the thermostat after a definite time interval, each tube was plunged into the bath at 70–80° for thirty seconds, cooled to ordinary temperatures by water, and analyzed as soon as convenient. Essentially the same method of analysis was employed as in assaying the pure bromohydrazobenzene, except that no aniline was used. The reason for this change was that in neutral or alkaline solution, a dark discoloration<sup>3</sup> which interfered with the sharpness of the end point, appeared on oxidation of the decomposed hydrazo solution. This was entirely avoided by carrying out the oxidation in slightly acid solution, and accordingly, the acid formed by the decomposition was not neutralized by the addition of aniline nor of acid ammonium carbonate. On the other hand, since aniline is formed by the decomposition, it was found necessary, after the decomposition had been allowed to proceed for some time, to add a small

<sup>1</sup> See Wieland, *Ber.*, 48, 1104 (1915) and the theoretical part of this article.

<sup>2</sup> Curme, *Loc. cit.*, p. 1156.

<sup>3</sup> According to Wieland (*Ber.*, 48, 1104) this is due to some semidine formed when hydrazobenzenes are heated in alcohol solution.

amount of 0.1 *N* HCl solution to the iodine solution before introducing the hydrazo solution, in order to have the oxidation mixture acid, and thus obtain a sharp end point.

The results for *p*-bromohydrazobenzene in 0.2 and 0.05 molal solutions are found in Table I. The first column gives the time in minutes during which the tube was heated, the second and fourth the number of grams of 0.1 *N* iodine solution required for 5 cc. of the hydrazo solution in two separate experiments, the third and fifth the values of the corresponding constants for a monomolecular reaction, calculated from these data and the above equation, and the sixth column the average value of  $K_{\text{mono}}$ . For the sake of comparison, in the last column is given the velocity constant for a dimolecular reaction, calculated from the data given in the fourth column and Equation 7.

It will be noticed that the "constant" for bromohydrazobenzene, while not showing the inclination to droop exhibited by the "constants" for Curme's substances, varies slightly from concentration to concentration. As the first determinations in 0.2 and 0.05 molar concentrations were run simultaneously, the difference in the constant for the two concentrations cannot be ascribed to an unobserved change of temperature of the thermostat.

Since the original theory of the reaction had to be abandoned as a result of the study of the products of the decomposition (see the theoretica

part), the velocity was next measured in exceedingly dilute solutions in order to determine whether the order of the reaction changes with extreme dilution. •For the analytical data, 0.05 *N* and 0.1 *N* solutions of iodine and sodium thiosulfate were used as indicated, and 10 cc. of the hydrazo solution used for each titration. Whereas the results (Table II) show values for a dimolecular reaction constant within experimental error in any one series, the constant in 0.005 molar is practically three times the constant in 0.01 molar concentration. The values of the monomolecular constant fall off decidedly in any series in these very dilute solutions, but the average value for *all* the concentrations used varies only from  $199 \times 10_5$  in 0.2 molar to  $258 \times 10_5$  in 0.005 molar; while the average value for the dimolecular constant in 0.2 molar is only one one-hundredth of the constant in 0.005 molar (0.0184 to 1.27).

The order of a reaction is tested more exactly by the constancy or inconstancy of the velocity constant in two solutions of differing initial concentrations, than by its constancy through the course of the reaction in any one solution. An exact expression for the order of a reaction, involving solutions of differing initial concentrations, has been developed by A. A. Noyes:<sup>1</sup>

$$n = 1 + \frac{\ln t_1/t_2}{\ln c_2/c_1},$$

where  $n$  is the order of the reaction, and  $t_1$  and  $t_2$  are the time intervals required for the reaction to proceed to equal fractions of the original concentrations,  $c_1$  and  $c_2$ .

In order to test the reaction in question by means of this equation, the percentages of decomposition in terms of the concentrations after 90 minutes at 145° were calculated from the data in Tables I and II, and the results plotted. The times required for a given percentage decomposition were found from this graph, and the values substituted in Noyes's equation. Tabulation of the results thus obtained will be found in Table III.

From these values of  $n$ , there can be no question as to the order of the reaction. The largest values are found for the more concentrated solutions where the velocity constants for a monomolecular reaction are unambiguous; and in these cases, the differences from unity are inconsiderable. Comparison of the two more dilute solutions gives values decidedly below one, which shows that in spite of the constancy of the value of  $K$  for a dimolecular reaction in each of these solutions by itself, the reaction is not dimolecular.

A study of the velocity constants of the decomposition of 2,4-dichlorohydrazobenzene (Table IV), shows that with this substance the monomolecular constant, which remains unchanged through a run in 0.1 molal

<sup>1</sup> Cf. Kremann, *Monatsh.*, 27, 611 (1906).

solution, falls off<sup>1</sup> toward the end of the run in a concentration (0.05 molar) where the constant for bromohydrazobenzene is still good. The average values<sup>2</sup> of the constant for the chlorohydrazo compound agree very well in the two concentrations. In the third and lowest concentration used (0.01 molar), the monomolecular constant falls off still more decidedly, as would be expected from the results with bromohydrazobenzene, but the dimolecular constant, on the other hand, shows a tendency to rise, which is not the case with the bromohydrazo compound in solutions less than 0.015 molal. Just as before with bromohydrazobenzene, the dimolecular constants for dichlorohydrazobenzene vary greatly from concentration to concentration, and this substance supports the evidence against a dimolecular reaction.

**4. Parallel Determinations of Hydrazo Compound Consumed and Amines Formed.**—In Curme's work on hydrazobenzenes, he calculated the velocity constant for the decomposition by means of the increasing amounts of aniline formed, and found that this method of analysis also gave a velocity constant according to the law for a monomolecular reaction, with only a slightly lower value than that obtained from the analytical determinations of the undecomposed hydrazo compound.<sup>2</sup> The method was indirect in that the amount of hydrazobenzene present at any instant of time was *calculated* from the experimentally determined concentration of hydrazo compound at the beginning of the run and the amount of aniline present at the time considered. In the following experiments on *p*-bromohydrazobenzene, the amounts of hydrazo compound as well as the amounts of amine present, were determined *experi-*

<sup>1</sup> A part but not all of this drop of 33 1/3% might be attributed to experimental error. No duplicate determination was made, owing to lack of time and the difficulty of preparing the substance.

<sup>2</sup> Curme, *Loc. cit.*, p. 1163.

mentally in each case; *i. e.*, four tubes, each containing 5 cc. of the solution, were removed from the thermostat at one time, the contents of two of them analyzed as above for bromohydrazobenzene by oxidation with 0.1 *N* iodine, and the contents of the other two for amines by separation through steam distillation as above, and bromination of the acidified distillate with 0.1 *N* potassium bromate. It has already been shown that the two amines occur in equimolecular proportions; the equation for the bromination is therefore

Since two mols of amine are formed by the decomposition of *two* mols of hydrazo compound, one cc. 0.1 *N* potassium bromate corresponds to 0.00002 mol hydrazo compound.

In Table V we find in the first column the time in minutes during which the tubes were heated, in the second the number of grams of 0.1 *N* iodine required for 10 cc. of solution, and in the third the corresponding number of mols of unchanged hydrazo compound per liter, calculated from consideration of the fact that one cc. 0.1 *N* iodine to 10 cc. solution is equivalent to 0.005 mol hydrazine per liter. In the fourth column is given the number of cubic centimeters of 0.1 *N* potassium bromate solution required for 10 cc. of the hydrazo solution, and in the fifth the number of mols hydrazine decomposed per liter. In the last column are given the sums of the concentrations in the third and fifth columns, *i. e.*, the total concentration of the hydrazo compound, decomposed and undecomposed. If there is no interfering reaction by which bromohydrazobenzene is used up without producing amine,<sup>1</sup> the numbers in the last column should be constant. This is the case within the limit of the experimental error, which is rather wide here, since it is the sum of the possible error in the iodine analysis and the error in the bromate analysis.

Table VI gives, in exactly similar form, the results of duplicate experiments on less concentrated solutions. In neither concentration is there any indication of a secondary reaction which is not negligible, nor is there any difference between the two concentrations.

<sup>1</sup> According to Wieland's work, published since this was written, small amounts of the hydrazobenzene suffer a semidine rearrangement under the conditions used (Wieland, *Loc. cit.*).

**5. Gaseous Products of Decomposition.**—In order to determine whether any hydrogen could be detected as a product of the thermal decomposition of hydrazobenzenes, an approximately molal solution of *p*-bromohydrazobenzene (10 cc.) was heated for 12 hours at 145° in two tubes which had been sealed off at a pressure of 10 mm. After cooling, the tubes contained a dark blue crystalline mass. When they were opened under a eudiometer filled with water, a very small bubble of permanent gas appeared—perhaps 0.03 cc. from each tube.

Since the solid product of the reaction made it seem possible that the reaction might have gone somewhat differently in this molal solution than in the more dilute solutions used in the velocity experiments, tubes containing 0.05 and 0.01 molal solutions were tested in a similar manner. From a tube containing 5 cc. of either solution with 6.5 cc. free space, which had been sealed off in a freezing mixture at 18 mm., and heated twelve hours at 145°, was obtained 0.7 cc. permanent gas at room temperature. Since the gas contained in 6.5 cc. at 0° and 18 mm. could give only 0.17 cc. at 20° and 760 mm., there must be some gas evolved during the heating, the nature of which was investigated in the following experiment: 50 cc. of 0.01 molal solution of bromohydrazobenzene were sealed off at 18 mm. in a bomb-tube of 125 cc. capacity, and heated for 10 hours at 145°. The tube was then opened under an inverted buret filled with water, and the gas transferred to a gas buret, and tested for hydrogen by passage over palladium black at 95°, after the oxygen present had been removed with pyrogallol. The volume of gas obtained from the tube was 4.6 cc. which was decreased to 4.35 cc. by the pyrogallol absorption. Treatment with palladium black reduced this volume only 0.05 cc.; and a subsequent attempt to explode the gas with the electric spark after admitting 12 cc. of air had no effect whatever. It is therefore certain that the gas obtained is not hydrogen, and that it can contain at most very small quantities of hydrogen, if any; and the small amount of oxygen shows that it cannot have been residual air due to imperfect evacuation

of the tube. There remains the possibility of some slight secondary decomposition of the hydrazo compound which involves evolution of nitrogen.<sup>1</sup>

**6. Effect of Molecular Hydrogen on Hydrazobenzene.**—To exclude the possibility that molecular hydrogen might react with hydrazobenzenes under the conditions of the experiments, an approximately 0.5 molal solution (5 cc.) was sealed off in a tube suspended in ice, with a stream of hydrogen at atmospheric pressure passing through it. The tube was then heated for two hours at 145°, cooled, and opened under a eudiometer. The volume of permanent gas obtained over water at 20° was 18.9 cc., while the volume of the tube above the solution was 17.15 cc.; 18.9 cc. at 20° corresponds to 18.2 cc. at 10°, which is about the temperature at which the tube was sealed off. Roughly, therefore, 1 cc. excess gas was found, and no appreciable amount of hydrogen was consumed by the hydrazo compound.

**7. Molecular Weight in Alcoholic Solution.**—There still remained the possibility that association of the hydrazo compound might account for the fact that the decomposition appeared as a monomolecular reaction, and that the decomposition of these complex molecules was the reaction of which the velocity was measured. The molecular weight of *p*-bromohydrazobenzene in absolute alcohol was therefore determined, and the evidence obtained was decisively against any association, as Table VII shows. McCoy's boiling point apparatus was used. In the following tabulation of the results, the first column contains the observed change in boiling point ( $\Delta$ ), the second the corresponding volume ( $V$ ) of solution in which the given weight ( $W$ ) of substance was dissolved, and the last column the molecular weight calculated from these data by means of the equation:

$$\text{Molecular weight} = \frac{W \times T}{\Delta \times V},$$

where  $T = 1560$  for alcohol.<sup>2</sup> The concentration of the solution at the beginning of the experiment was approximately 0.2 molar.

**A CATALYTIC DECOMPOSITION OF CERTAIN PHENOL SILVER SALTS.**

[FIRST PAPER.<sup>1</sup>]

By W. H. HUNTER, A. O. OLSON AND E. A. DANIELS.

Received July 8, 1916.

During the progress of work on the chromoisomeric silver salts of some halogenated phenols, it was observed by Torrey and Hunter<sup>2</sup> that both the red and white silver salts of tribromophenol, if absolutely dry, reacted in a very unusual way with dry undiluted ethyl iodide. The iodide solutions rapidly assumed a deep blue color, which faded a little more slowly, giving way to a brownish yellow. A precipitate remained which consisted mainly of silver bromide with a little iodide, while the ethyl iodide held in solution a white amorphous compound, which could be precipitated by alcohol. This compound could also be obtained by the use of other alkyl iodides, but the different preparations were practically identical in bromine content, showing that no alkyl group had been introduced. Direct tests showed a complete absence of silver and iodine.

At this point the work was dropped, as it offered no immediate assistance in the study of the silver salts. The reaction possessed considerable intrinsic interest however, because it was so different in all respects from the expected alkylation. On this account, work on the change has since been taken up in this laboratory, and the present paper embodies that part of the work which is concerned with the composition of the white amorphous compound, the preparation of analogous compounds, their genetic relation to the parent silver salts, and the nature of the reaction by which they are formed.

**The Composition of the White Amorphous Compounds.**—On taking up the work again, the amorphous compound from tribromophenol was analyzed for carbon and hydrogen, and its molecular weight was determined cryoscopically, when it was found that it possesses the formula  $(C_6H_2Br_2O)_n$ . Its physical properties are entirely in accord with this formula, as it is completely amorphous, and very soluble in organic liquids containing halogen, but swells up before dissolving, and on evaporation of the solvent is left as a yellow-brown varnish. Slowly heated in a melting point tube, it commences to shrink at about 260°, gradually sintering and turning darker, until at about 290° it is almost black. On account of these properties it could only be purified by alternate solution in ethyl iodide or chloroform, and reprecipitation with alcohol, and its purity could only be tested by analysis of successive fractions obtained

<sup>1</sup> Some of the work described in this paper was presented in abstract at the Eighth International Congress of Applied Chemistry, New York, September, 1912.

<sup>2</sup> THIS JOURNAL, 33, 204 (1911).

in this manner. Until further information as to its constitution can be brought forward, it is suggested that it be called polydibromophenylene oxide.<sup>1</sup>

Having ascertained the composition of the white amorphous compound, it became necessary to find out whether other compounds of analogous properties could be obtained from other phenols in like manner. For this purpose, as most like the tribromophenol, were chosen the symmetrical trichlorophenol, and the tribromoresorcinol monomethyl ether, which differs from tribromophenol only by a methoxyl group.

The silver salt of the last named phenol was found to behave in exactly the same way with alkyl iodides as that from tribromophenol, except that the blue color was more persistent. The oxide from this phenol proved to have a bromine content and molecular weight corresponding to that expected, and may be called polydibromomethoxyphenylene oxide. This silver salt soon proved to be very much better suited to a study of the decomposition than the tribromophenolate. For instance, simple covering of the salt with pure benzene is sufficient to induce the whole series of changes, starting in with the blue color, and ending with the formation of a solution of the amorphous oxide, which could be isolated by precipitation with gasoline.

On the other hand, silver trichlorophenolate gave but a slight abnormal reaction with cold ethyl iodide, forming almost no amorphous compound, but yielding trichlorophenetol instead. However, a short heating in benzene brought about the smooth decomposition of the salt, and there was obtained an oxide in every respect analogous to the others.

**The Equation for the Reaction.**—In these three cases, then, a compound had been obtained of a composition corresponding to the original silver salt minus a molecule of silver halide, but of very high molecular weight. In order to see if there might be any other products formed, a weighed sample of the silver salt from the resorcinol derivative was allowed to stand with cold ethyl iodide, and the reaction product was investigated. It was found that within the limit of error of the experi-

<sup>1</sup> This compound is probably identical with that obtained by Kastle and Loevenhart (*Am. Chem. J.*, **27**, 34 (1902)) by the action of sunlight on a solution of tribromophenolbromide. To this compound, though colorless, Kastle and Gilbert (*Am. Chem. J.*,

**27**, 52 (1902)) ascribe tentatively the formula 
$$\text{O} = \text{C} \begin{array}{c} \text{Br} \quad \text{H} \\ \diagup \quad \diagdown \\ \text{C} = \text{C} \\ \diagdown \quad \diagup \\ \text{C} = \text{C} \\ \diagup \quad \diagdown \\ \text{Br} \quad \text{H} \end{array} \text{C} = \text{C} \begin{array}{c} \text{H} \quad \text{Br} \\ \diagup \quad \diagdown \\ \text{C} = \text{C} \\ \diagdown \quad \diagup \\ \text{C} = \text{C} \\ \diagup \quad \diagdown \\ \text{H} \quad \text{Br} \end{array} \text{C} = \text{O}$$

which is analogous to the formula now ascribed to the red compound known variously as "Lautemann's red," "diiodo phenylene oxide," and "tetraiodo diphenylene quinone." (Cf. Wilsie, *J. Soc. Chem. Ind.*, 1910.) These interesting relationships will be discussed in a future paper.

ment, the silver salt had been quantitatively transformed into amorphous oxide and tribromoresorcinol methyl ethyl ether, no other products being found.

Obviously, then, the ethyl iodide does not appear in the equation for the formation of the oxide, which will be as follows for the case of the silver tribromophenolate:

**The Mechanism of the Decomposition.**—An attempt at accounting for this action led to the formation of the following hypotheses:

1. The reaction may be intermolecular, the silver atom of one molecule uniting with a bromine from another molecule of the salt, to split out silver bromide and form a chain of rings.
2. The intermolecular reaction may be confined to two molecules, or a very few, which give a residue of low molecular weight, which polymerizes.
3. There may be an "intermediate addition" of alkyl halide, with the formation of a blue compound, and a subsequent splitting out of silver halide and alkyl halide. This would mean the formation of a simple molecule which could polymerize to the white oxide.
4. The decomposition may be strictly intramolecular, a decomposition of the silver salt itself, the silver atom uniting with a bromine atom from its own molecule, to leave the simple residue, which then polymerizes to form the oxide.

The hypotheses concerned with intermolecular reactions seem to be eliminated by the following considerations:

1. The silver salt of the resorcinol derivative decomposes on wetting with benzene, which has very little solvent action on silver salts.
2. Ethyl iodide in vapor form acts on dry salt as if diluted with a solvent such as ether, bringing about an alkylation, with no decomposition. Evidently liquid ethyl iodide is necessary for the new change. It is equally unlikely that the salt dissolves in ethyl iodide.
3. There is no reason for supposing that silver could easily remove halogen attached to the ring, even if the salt were dissolved. Slight solution is more probable in alcohol, where ethyl iodide gives a normal alkylation.
4. There is no silver in the amorphous oxide, or in the blue resins left on evaporation of benzene solutions of the fresh reaction product. It is hard to see how every atom of silver could be removed from the amorphous compound by an intermolecular reaction, which would be expected to leave a silver atom on one end, and a bromine atom on the other end of a long chain of rings.

The next hypothesis, of an addition compound, was easily disposed of by showing that the smooth decomposition could be brought about by heat alone, or by warming to a slightly lower temperature, and "setting

off" the salt with a minute amount of a reactive substance such as ethyl iodide or chlorine. The reaction would then proceed by its own heat, which proved to be sufficient to raise the temperature of one sample from 100° to 180°.

Samples of the oxide produced at these high temperatures were analyzed for bromine. They proved to have a slightly lower content than the theoretical, giving a little over 1% less than the required amount of bromine. It is more surprising that the result should be so close than that a difference should exist, because it must be supposed that more deep-seated changes would certainly occur at the temperatures reached in the decomposing mass of salt, and it would probably be especially difficult to remove such products entirely from the oxides. Nevertheless, there can be no doubt that even at this relatively high temperature, the formation of silver bromide and amorphous oxide is practically the only reaction occurring. A quantitative determination of reaction products proved impossible in this case, on account of the extreme fineness of the silver bromide formed, which became suspended in colloidal form in all solvents, and rendered the purification of the oxide very difficult. No other products than bromide and oxide, however, could be demonstrated in the reaction mixture, and only the low halogen content indicated the presence of other reactions.

These results show conclusively that the reaction can be brought about without any solvent, by heat alone. They also show that reactive substances have a fuse-like action on salt which is heated to a temperature just insufficient to bring about decomposition of the type studied.

This fuse-like action is probably entirely analogous to the decomposition at low temperatures, which is seen in its extreme form in the decomposition of the silver salt of the monomethyl ether of tribromoresorcin on covering with thiophene-free benzene in a desiccator. Light is apparently not necessary for this change, as it starts first in any deep crack in a lump of salt, which on being opened, will be found completely filled with blue solution. It seems to be due to contact of the benzene with the salt, so that we have the unusual case of a liquid catalyzing a change occurring in a homogeneous solid. Since the deep color is reminiscent of Vorländer's addition compounds of type A, it may be well to insist again upon the absence of silver in the blue varnishes obtained, and upon the fact that the color of these varnishes goes over completely into the light yellow of the amorphous resin left by solutions of the oxides. Further, the action of ethyl iodide vapor in giving the ether instead of the amorphous oxide, while benzene causes the oxide formation, seems to indicate that the presence of actual liquid is more important than the chemical individual it represents. Up to the present time, no experiments have been devised, which can settle the question as to whether the solid dissolves somewhat,

the reaction then occurring in solution, or whether strong adsorption of the benzene or ethyl iodide occurs, followed by decomposition of the surface layers of the solid. This is one of the most interesting points about the change, and it is hoped that some way may be found by which the precise action of benzene may be established. It would be especially interesting in view of Langmuir's late work on adsorption and heterogeneous reactions, on account of the fact that the crystalline white silver salt of tribromophenol reacts just as does the apparently amorphous red form. It does not seem wise to take up this phase of the problem until all other parts of the work shall have been cleared up as far as possible.

The reaction is somewhat like those smooth decompositions of silver salts studied by Angeli and others,<sup>1</sup> one of which they represent by the

contrasted with that of Burke and Donnan,<sup>2</sup> who found that alkyl halides in alcohol act on silver nitrate to give two reactions, represented by the equations

Several interesting problems are raised by the acceptance of the simple decomposition, some of which are still being investigated. It seems worth while to mention two of them at this point.

The first one is that of the blue color. So far, no expedient has been devised, which permits the isolation of a blue compound. All the data so far at hand lead to the view that the blue compound is a polymer of the unsaturated residue, lower than the white oxide—even conceivably the unsaturated residue itself—or that it may be related to coerulignone.

Far more important is the following problem: If the hypothesis of a simple monomolecular reaction is correct, how can it be brought about in one case by heat, in another case by a reactive substance such as ethyl iodide, that can and does react with other molecules of the phenolate at the same time, and in yet a third case by a substance, benzene, which presumably does not react with it in the ordinary sense of the word?

It may, perhaps, be temporarily viewed as a result of at least two factors, of which one is the known instability of silver salts, and the other the presence in the molecule of a benzene ring loaded with halogen atoms in the critical ortho and para positions. It may be conceived that in such a molecule, the silver atom would be unusually closely related to one of the halogens, whether by being actually on the same carbon atom, as sug-

<sup>1</sup> Angeli and Alessandri, *Atti accad. Lincei*, 18, 38 (1909); 18, 784 (1910); Angeli and Marchetti, *Ibid.*, 17, 695 (1908).

<sup>2</sup> *Trans. Chem. Soc.*, 85, 555 (1904); *Zeit. physik. Chem.*, 69, 148 (1909).

gested for the colored forms by Torrey and Hunter,<sup>1</sup> or better in some other way, which could be equally applicable to all of these salts. In such a molecule there would be considerable tendency for decomposition to occur in such a way as to split out silver bromide in just such a manner as occurs with our salts. In other words, there would be a strain in the molecule, which would not be sufficient to bring about a spontaneous decomposition of the pure dry salt, but which would determine the line of fission of the molecule when gently heated.

When the salt is not heated, but is covered with benzene, the effect of solution, or, as has been already suggested, of adsorption—in either case, the intimate approach of molecules of liquid and salt, must bring about changes comparable to those of ordinary surface catalytic effects—perhaps comparable more nearly to Baly's ideas of chemical change.

Further work is in progress along several lines opened up by this view of the salts and their decomposition, which is intended to serve at present simply as a working hypothesis.

### Summary.

The silver salts of the following phenols

suffer a smooth decomposition into silver halide and an amorphous polymerized residue, in the sense of the following equation:

This occurs readily on suspension of the salt in alkyl iodides, or in pure benzene.

The same effect is produced by heating to temperatures slightly above 100°.

It is suggested by the authors that this may be due to a stress existing in the molecule of the silver salt; between the silver atom and the halogen which goes out with it, not sufficient to cause decomposition until some catalytic effect is exerted on the molecule from without.

### Experimental Part.

**Preparation of the Silver Salts of the Phenols.**—Since the phenols used are but slightly soluble in water, but give soluble alkali salts, quite strongly hydrolyzed, the following procedure has been used for the preparation of their silver salts:

The pure phenol was dissolved in a slight excess of twice normal potassium hydroxide solution, as free from halogen as possible, and after considerable dilution 1% acetic acid was added to the mixture with

<sup>1</sup> *Loc. cit.*

stirring, until a slight permanent precipitate of the phenol was obtained, indicating a neutralization of the excess alkali. A few drops of very dilute silver nitrate were then added, and the solution was well stirred to insure opportunity for the precipitation of any halogen ion present.

The mixture was then allowed to stand for a while, and filtered without suction. A clear bright solution resulted, which gave a voluminous precipitate of the desired silver salt on addition of silver nitrate. The silver salts of the three phenols used in this work were all known—the one from trichlorophenol is yellow, the one from tribromoresorcinol monomethyl ether is white, and the one from tribromophenol is one of Torrey's<sup>1</sup> silver salts, and exists in two modifications, a red and a white.

This precipitate was allowed to stand in the dark for an hour or more, to allow it to become granular, and then filtered without suction, with washing on the filter till the wash water gives only a slight opalescence on testing for silver—the silver salts themselves are slightly soluble in water. It was then transferred to a Buechner funnel, sucked dry, partly dried by continuing the suction, and transferred to clean glass watch glasses, spread out thin. It was allowed to dry by standing in clean air in the dark, and finally in a desiccator in the dark, best over calcium chloride. In this way very pure samples of silver salts were obtained, which could be kept for a long time without signs of change.

**Experiments with Tribromophenol Derivatives.**—Some of the polydibromophenylene oxide was made by the action of ethyl iodide on the red silver salt of tribromophenol, as described by Torrey and Hunter.<sup>2</sup>

Subst. 0.2187; CO<sub>2</sub>, 0.2348; H<sub>2</sub>O, 0.0199. Subst. 0.1500; AgBr, 0.2260.

Calc. for C<sub>6</sub>H<sub>2</sub>Br<sub>3</sub>O: C, 28.81; H, 1.02; Br, 63.99. Found: C, 29.28; H, 1.02; Br, 64.12.

The silver halide from the Carius determination was treated with zinc and sulfuric acid, and the solution tested for iodide with chloroform and bromine water, but none was found.

**Molecular-weight Determination.** This was carried out with recrystallized bromoform as solvent.  $K = 144$ . (Freezing point.)

Solvent, 30.19 g.; subst. 0.207, 0.332;  $\Delta$ , 0.008°, 0.024; Mol. wt., 12,400, 6,600.

**Decomposition of Silver Trichlorophenolate.**<sup>3</sup>—About two grams of the silver salt were placed in an Erlenmeyer flask with 50 cc. of benzene, and the mixture was heated under a reflux condenser on a water bath at 60° for about thirty minutes. The solid remaining at the end of this time was light gray in color, and very finely divided. A great deal of trouble was encountered in obtaining a clear solution, but this was finally accomplished by many filtrations without suction. The clear benzene solution

<sup>2</sup> *THIS JOURNAL*, **33**, 204 (1911).

<sup>3</sup> The work on trichlorophenol was performed by Mr. L. Karatz.

was then completely precipitated by gasoline. An amorphous compound entirely similar in appearance to the one from tribromophenol was obtained, which was purified by alternate solution and reprecipitation with benzene and gasoline and analyzed for chlorine.

Subst. 0.1236, 0.1030, 0.2186 and 0.2008; AgCl, 0.2221, 0.1804, 0.3896 and 0.3565.

Calc. for  $C_6H_2Cl_2O$ : Cl, 44.09. Found: 44.74, 43.61, 44.11, 43.98. Av. = 44.11.

**Action of Ethyl Iodide.**—The chief effect of ethyl iodide is the formation of the trichlorophenetol. Very little amorphous oxide can be obtained in this way, but it can be demonstrated as a reaction product.

**Work on the Silver Salt of Tribromoresorcinol Monomethylether.**

**Decomposition by Ethyl Iodide.**—On covering the dry salt with ethyl iodide the characteristic blue color developed very much more quickly than with the tribromophenol salt, and lasted very much longer. The amorphous white compound was easily obtained by precipitating it with alcohol, though it was at first colored green by adhering blue compound.

Subst. 0.1486; AgBr, 0.1998. Calc. for  $C_6H(OCH_3)Br_2O$ : 57.11. Found: 57.25.

In order to see if any other products were formed, than silver bromide, iodide, the oxide, and the methyl ethyl ether of tribromoresorcinol, 0.811 g. of the salt was covered with pure ethyl iodide, and allowed to stand twenty-four hours. The mixture was then separated by filtration, and the silver salts were washed well, the filtrate and washings being received in a weighed beaker.

The residual silver salt weighed 0.361 g.

The mixture of oxide and ether was heated in the flask in boiling water, but could not be brought to a constant weight, apparently because of slow volatilization of the ether, which crystallized out on the walls of the flask. The observed weight of these products was 0.546 g. No products other than ether and oxide were found.

Now, if all the salt had been converted into oxide and silver bromide, the latter would have weighed 0.326 g., and the oxide, 0.485 g.

This excess in weight of silver residue is due to the weight of iodine in excess of the equivalent bromine,  $I - Br = 0.35$  g.

The total excess weight of both residues is equal to the whole of the ethyl iodide added to the salt, and is 0.096 g.

Calculated from the silver residue, this should be 0.116 g., if only these two reactions occurred.

This is two centigrams of error in ninety-one centigrams, not twenty per cent. of error, and since a loss of the phenol ether from the organic residue would account for part of this, by diminishing the total excess weight, it is not surprising that the result is not closer. Also, some silver bromide might have been transformed into iodide by standing twenty-four hours in ethyl iodide, and this would have increased the silver residue,

but would also have increased over much the calculated weight of ethyl iodide added. Further, no other products have ever been isolated from these reaction mixtures.

**Tribromoresorcinol Methyl Ethyl Ether.**—This is formed at the same time as the amorphous oxide, and can be obtained from the filtrate after precipitation of the oxide by alcohol. Long, hard needles from alcohol and water. Melts at  $75^{\circ}$ . Soluble in ordinary solvents.

Analysis for bromine:

Subst. 0.2593 and 0.3251; AgBr, 0.3756 and 0.4700.

Calc. for  $C_6HBr_3(OCH_3)(OC_2H_5)$ : 61.67. Found: 61.64, 61.50.

#### Molecular-weight Determination on the White Oxide.

This was carried out, using benzene as solvent, by the cryoscopic method. Solvent, 16.0 g. Subst. 0.3530,  $0.2573$ ;  $\Delta$   $0.049^{\circ}$ ,  $0.011^{\circ}$ . Mol. wt. 2250, 7308.

#### Decompositions at Low Temperatures.

**Silver Salt of Tribromoresorcinol Monomethyl Ether:** *Action of Benzene.*—A pure, dry sample of silver salt was covered with thiophene-free benzene, and placed in a calcium chloride desiccator. In a short while a blue color developed, starting first at the larger lumps, and then diffusing away into the solution, which finally became very deep blue. No particular catalytic effect seemed to be exerted by the blue in solution. It was filtered from the solid residue, and the filtered solution was allowed to evaporate at ordinary temperature. The blue color slowly disappeared, and when the benzene had evaporated, a reddish yellow varnish was left, which had all the properties of the amorphous oxides.

A most interesting observation was made on a very pure sample of silver salt, which was washed as usual, and then heated with benzene before it had become entirely dry. The blue color appeared in this case also, and rather rapidly. Another pure sample was then heated with benzene. The blue color appeared immediately, and the same cycle of changes occurred, in much more rapid sequence. The filtered benzene solution, after disappearance of the blue color, gave a copious white precipitate of amorphous substance on the addition of either alcohol or ligroin.

*Cold Ethyl Iodide Vapor.*—0.1927 g. of dry salt was placed in a watch glass, and this suspended in a beaker a couple of inches above the bottom, which was covered with ethyl iodide. It was allowed to stand about seventeen hours, removed to the balance case, and weighed in one hour. It had gained 0.0471 g. in this time. Calculated gain for complete ether formation, 0.0642 g.

On investigation of the product, it was found that no recognizable amount of amorphous compound was present, but that the methyl ethyl ether of tribromoresorcinol was present.

*Ethyl Bromide.*—Some very pure ethyl bromide was made free from alcohol and ether and used soon after its manufacture.

It gave *no* blue color with Torrey's silver salts from tribromophenol on standing.

A sample of the silver salt of tribromoresorcinol monomethyl ether was covered with the ethyl bromide, and placed in a desiccator. After a time, the blue color developed where the salt was piled up highest.

Another sample partly in lumps was placed in the ethyl bromide without crushing. The blue color appeared first in the lumps.

It is interesting that ethyl bromide appears to stand nearer to benzene in its catalytic action than to ethyl iodide.

#### Decompositions at Higher Temperatures.

A thin layer of the silver salt was placed in a narrow porcelain boat about five inches long, and this was placed in the inner tube of a condenser. Steam was passed through the outer jacket of the condenser, and a thermometer was introduced near the salt. It soon registered over  $90^{\circ}$ , and in seven minutes had reached  $99.5^{\circ}$ . It was removed, and the salt heated about a minute longer. Then a flask containing pure ethyl iodide was attached to the condenser, and warmed. Immediately, even before the ethyl iodide had started to boil, a greenish blue patch appeared on the salt nearest the ethyl iodide. In a second or two, the blue color changed to a dull brown, and then this color spread rapidly away from this end of the boat, in one experiment requiring about five seconds to go twenty-five millimeters. An entirely solid residue was left in the boat, though the reaction was accompanied by a curious appearance of fusing or sintering of the salt. Fine particles were also seen to fly up a little distance from the mass, so several samples were weighed out, to see if any amount of substance was being lost in this way, or as a gas.

0.7455 g. lost 0.0047 g. 0.8390 g. lost 0.0032 g. 0.6540 g. lost 0.0051 g.

Another weighed sample was heated alone, without treatment with ethyl iodide. It did not decompose.

0.4426 g. gained 0.0018 g.

It was then treated with iodide vapor as the other samples, when it decomposed, and gained 0.0013 g. more.

The same experiments were tried, using chloroform vapor instead of steam, and the same decomposition was found to occur.

Another sample was lightly packed into a pear-shaped bulb made from a test tube, and a thermometer bulb was inserted into the middle of the salt. It was then heated with live steam until the thermometer registered  $99.5^{\circ}$ , when a very small amount of ethyl iodide was squirted into the bulb so as to touch the silver salt. This decomposed immediately as before, and very soon the temperature commenced to rise, until it reached a maximum of  $185^{\circ}$ .

**Experiments in Tubes.**—Pieces of ordinary glass tubing, 125–150 mm. long, were sealed at one end and cleaned thoroughly. One was filled

with silver salt, and then placed in the steam jacket. After five minutes of heating, the ethyl iodide was let in. The expected green patch appeared at the open end, and then the decomposition proceeded through the tube as in the boat.

Another tube was half filled with silver salt, a layer of sand was placed on it, four or five millimeters in thickness, and the rest of the tube was then filled with more silver salt. The reaction proceeded to the sand only.

In another tube, even less sand was used, the layer being but two or three millimeters thick, in order to avoid contact between the two divisions of the salt. The action again ceased at the sand.

Several samples of these residues were combined and extracted with benzene. This solution was treated with fullers' earth, filtered, and ligroin was added to the reddish solution, when a pink precipitate was obtained. This was redissolved in benzene and reprecipitated six times, and the final product, still slightly pink, was analyzed for halogen.

Subst. 0.1655 and 0.1595; AgBr 0.2179 and 0.2100.

Calc. for  $C_4H(OCH_3)Br_2O$ : Br, 57.11. Found: 56.03, 56.03.

#### Effect of Other Substances.

The following substances, in small amounts, were found to cause the decomposition of preheated salt: Propyl bromide, chloroformic ester, concentrated hydrochloric acid, fuming nitric acid, iodine, and bromine.

MINNEAPOLIS, MINNESOTA.

### HYDRAZINO DIACIDS.

By J. R. BAILEY AND L. A. MIKESKA

Received June 12, 1916.

#### Introduction.

The first hydrazino diacid, hydrazinodiacetic acid,  $NH_2N(CH_2COOH)_2$ , was discovered in the Heidelberg laboratory by Curtius and Hussong.<sup>1</sup> The method of preparing this substance was improved by Bailey and Read and its reactions further investigated.<sup>2</sup> Darapsky and Prabhakar have announced the discovery of hydrazinodimalonic acid,<sup>3</sup> the second hydrazino diacid thus far reported, but the work described in this article shows that the proofs deduced for the constitution of this substance are not valid.

Hydrazinodiacetic acid is readily made by the action of monochloroacetic acid on hydrazine in alkaline solution, and as the product is difficultly soluble in water, its isolation presents no difficulty. It might be expected that other halogen acids would produce similar results with hydrazine, and that the solubilities in water of the hydrazino diacids thus formed

<sup>1</sup> *J. prakt. Chem.*, [2] **83**, 249 (1911).

<sup>2</sup> *THIS JOURNAL*, **36**, 1748 (1914).

<sup>3</sup> Moreswar Prabhakar, *Dissertation*, Heidelberg, 1912.

would also render them easily separated from the inorganic admixtures produced in their preparation. The other common  $\alpha$ -halogen acids react beyond question on hydrazine in alkaline solution, but on neutralizing the reaction mixtures there is no separation of the expected hydrazino diacids. It might be supposed that, even were the hydrazino diacids readily soluble in water, their isolation could be effected by converting them to the corresponding benzylidene compounds, since all hydrazines, as a rule, readily condense with aldehydes and ketones in the well-known way. However, Curtius and Hussong failed to produce a reaction between hydrazinodiacetic acid and aldehydes as is evidenced by the following quotation from the article referred to above:

"Alle Versuche, die Säure mit Aldehyden zu kondensieren, verliefen ohne Ergebnis. Angewandt wurden: Benzaldehyd, Salicylaldehyd, *m*-Chlorbenzaldehyd, und *m*-Nitrobenzaldehyd. Weder in neutraler, noch in saurer oder alkalischer wässriger Lösung, weder beim unmittelbaren Zusammenbringen der Körper bei gewöhnlicher Temperatur, noch beim Erwärmen trat Kondensation ein."<sup>1</sup>

This peculiar anomaly of hydrazinodiacetic acid, as reported by the German investigators, induced us to institute experiments aimed at establishing conditions under which hydrazinodiacetic acid could be made to react normally with aldehydes. Contrary to the observation of Curtius and Hussong, we find that benzaldehyde reacts smoothly and normally with hydrazinodiacetic acid in aqueous solution, giving a practically quantitative yield of benzylidenehydrazinodiacetic acid, while in potassium hydroxide solution both benzaldehyde and salicylaldehyde condense with this hydrazine, giving hydrazones that can be isolated in the form of the difficultly soluble monopotassium salts. Attention may be directed to the fact that, if neutral potassium hydrazinodiacetate be condensed in water solution with benzaldehyde and then sufficient sulfuric acid added to neutralize all the potassium, the hydrazone separates partly as monopotassium hydrazinodiacetate,

and partly as the free hydrazone acid. The hydroxybenzylidene compound, prepared similarly, separates only in the form of its monopotassium salt. In other words, these potassium salts are stable in the presence of a mineral acid.

The discovery of hydrazone derivatives of hydrazinodiacetic acid gave an incentive to attempts in the preparation of other hydrazino diacids. The method of Curtius and Hussong, as modified and improved by Bailey and Read,<sup>2</sup> can be extended to the preparation of other hydrazino diacids than the diacetic acid derivative, where the acid rest is of a single type. In the case of mixed hydrazino diacids, such as hydrazinodiacetic-propionic

<sup>1</sup> *J. prakt. Chem.*, [2] 83, 275 (1911).

<sup>2</sup> *Loc. cit.*

acid, the method, for obvious reasons, would not be available. This latter purpose can be effected, as shown in this article, by the reduction of mixed nitrosimino diacids, a reaction employed by Bailey and Snyder<sup>1</sup> in the conversion of nitrosiminodiacetic acid to hydrazinodiacetic acid. Furthermore, in the experimental part of this article it is shown that benzylidenehydrazino monoacids are very reactive in alkaline solution toward  $\alpha$ -halogen acids. By this method both benzylidenehydrazinoacetic-propionic acid, and benzylidenehydrazinodipropionic acid were prepared from benzylidenehydrazinopropionic acid,  $C_6H_5CH = NNHCH(CH_3)COOH$ . Benzylidenehydrazino-*i*-butyric acid,  $C_6H_5CH = NNHC(CH_3)_2COOH$ , was converted similarly by this process to benzylidenehydrazinoacetic-isobutyric acid.

Bailey and Read,<sup>2</sup> and before them Busch and Walter,<sup>3</sup> showed that the imino hydrogen in hydrazones is reactive; the former added cyanic acid on to benzylidenehydrazino-*i*-butyric acid, producing 5-dimethyl-1-benzylideneaminohydantoin,

while the latter investigators with carbonyl chloride and benzylidenephénylhydrazine made benzylidenephénylhydrazinocarboxylic acid chloride,  $C_6H_5CH = NN(COCl)C_6H_5$ . In this article it is shown that cyanic acid in glacial acetic acid with benzylidenehydrazinopropionic acid yields methylbenzylideneaminohydantoinic acid,  $C_6H_5 - CH = NN(CONH_2)CH(COOH)CH_3$ . This observation may lead to a serviceable method of preparing unsymmetrical substitution products of phenylhydrazine, by the introduction of various acid rests on the  $\alpha$ -nitrogen.

In the work herein described the very unexpected observation has been made that the benzylidene compounds of the hydrazino diacids, with the exception of hydrazinodiacetic acid, on being precipitated from alkaline solution, even with a mineral acid in excess, retain a *half atom* of alkali metal. Benzylidenehydrazinoacetic-propionic acid, benzylidenehydrazinoacetic-isobutyric acid, and benzylidenehydrazinodipropionic acid, when precipitated from either potassium or sodium hydroxide solution, give beautifully crystallizing, snow white substances, on which careful determinations of C, H, N, and K, or Na, give concordant results for the above constitution. These peculiar alkali derivatives, which separate in the presence of an excess of mineral acid, can be recrystallized from glacial acetic acid unchanged. In an experiment with the potassium

<sup>1</sup> THIS JOURNAL, 37, 935 (1915).

<sup>2</sup> *Ibid.*, 37, 1892 (1915).

<sup>3</sup> *Ber.*, 36, 1359 (1903).

compound of benzylidenehydrazinoacetic-isobutyric acid the hydrazone was suspended in water, the calculated amount of sulfuric acid added to convert all the potassium present to potassium sulfate and solution effected by boiling. The solution was boiled for half an hour with steam passing through it. A part of the benzaldehyde in this process was eliminated, but on cooling a large part of the unchanged potassium salt crystallized out. As was to be expected, the liquid proved strongly acid toward congo paper. The formulas of these alkali derivatives, which are similar to potassium tetroxalate in their constitution, may be exemplified by the following interpretation of the potassium salt of benzylidenehydrazinodipropionic acid:

Experiments to obtain the three new hydrazino diacids in a form suitable for analysis were abandoned, because of their hygroscopic nature. Preliminary experiments have shown that they can be prepared in solution by converting the alkali salts of the benzylidene derivatives into the alcohol soluble sulfates of the hydrazinodiacids and removing the sulfuric acid in the usual way. When precipitated from an alcoholic solution with ether, these hydrazines quickly deliquesce on exposure to air. Their hydrazine nature is revealed by the fact that they condense normally with benzaldehyde like hydrazinodiacetic acid. The structure of hydrazinodipropionic acid has also been confirmed by converting it to ethyl semicarbazinodipropionate,

The benzylidene derivatives of three new hydrazino diacids have been prepared. They are all very readily purified by recrystallization from alcohol and uniformly contain a half atom of alkali metal in the molecule.

Conditions have been established for the preparation of benzylidene hydrazinoacetic-isobutyric acid. In contrast to most hydrazones, this substance is very soluble in water even at room temperature, which fact, coupled with the difficult solubility of the acid alkali salts, offers in part an explanation of why the alkali salts are formed exclusively on acidifying an alkaline solution of this hydrazone. The difference in the solubility of benzylidenehydrazinodiacetic acid and its alkali acid salts is not very marked, although the latter are more soluble in water than the former. Conductivity determinations carried out by Mr. W. A. Felsing, of this laboratory, show the benzylidenehydrazinodiacids to be comparatively strong electrolytes, *e. g.*, the ionization of benzylidenehydrazinodiacetic acid is about one-half that of oxalic acid.<sup>1</sup> The association of

<sup>1</sup> Conductivity determinations on benzylidenehydrazinodiacetic acid were made at 25° with the assumed ionization of only one H from the two carboxyls. The conduc-

four carboxyls in the alkali salts of three of the hydrazones of the hydrazino diacids discussed, plays no doubt an important rôle in determining their stability in the presence of mineral acids. Attention has been called to the fact that *hydroxybenzylidenehydrazinodiacetic acid*, in contrast to the simple *benzylidenehydrazone*, precipitates from an alkaline solution in the presence of a free mineral acid *only* in combination with the alkali metal. Here the acidifying influence of the OH group is self-evident.

As a further proof of the constitution of the peculiar alkali salts of the *benzylidenehydrazino diacids*, the synthesis of *hydrazinodipropionic acid* from *hydrazinomonopropionic acid* and  $\alpha$ -*bromopropionic acid* in alkaline solution was carried out. In this reaction the *hydrazinodipropionic acid* was isolated as the potassium salt of the *benzylidene derivative* and the latter proved identical with the preparation referred to above from *benzylidenehydrazinopropionic acid* and  $\alpha$ -*bromopropionic acid*. The interesting observation was made that not only is the unsymmetrical *hydrazinodipropionic acid* formed here but also the symmetrical tivity at infinite dilution used in the calculations below is taken as 457 ohms, this factor being deduced from the conductivity determinations carried out on the *monopotassium salt*.

Concentration.....	0.002 <i>M</i>	0.001	0.0005	0.0002
Conductivity.....	200.5	229.0	283.0	350.0
Ionization.....	43.86%	50.05	61.93	76.60

Conductivity determinations on the *monopotassium salt* of *benzylidenehydrazinodiacetic acid* from two stock solutions of 0.05 molar were carried out and the determinations made in duplicate showed uniformity.

Concentration....	0.05 <i>M</i>	0.02	0.01	0.005	0.002	0.001	0.0005
Conductivity....	87.8	95.1	100.1	105.7	118.7	132.4	150.1
Ionization.....	47.72%	51.40	54.10	57.15	64.15	71.60	81.20

Here the conductivity at infinite dilution was obtained by two methods: first, by plotting conductivity against concentration, which yielded the value 185; second, by the method of Noyes and Coolidge (*Carnegie Inst. Publ.*, No. 63, 50) of plotting  $1/L$  against  $(CL)^{n-1}$ . The best straight line was obtained with the  $n$  value at 1.625, yielding an  $L_\infty$  value of 188.7.

In order to determine the conductivity of the *free acid* at infinite dilution, the method was as usual:

$L_\infty$  salt —  $L_\infty K^+ + L_\infty H^+ = L_\infty$  acid, or substituting the two values of  $L_\infty$  for the potassium salt found above

$$185 - 74.8 + 347 = 457.2$$

$$188.7 - 74.8 + 347 = 460.9$$

By employing the method of Derick (*THIS JOURNAL*, 36, 2268 (1914)) for calculating the conductivity of weak acids at infinite dilution from measurements below a concentration of 0.02 *N*, the  $L_\infty$  value for *benzylidenehydrazinodiacetic acid* from the conductivity measurements at the two concentrations, 0.0005 and 0.0002 molar, was found to be 456. Of these three closely agreeing values, 456, 457.2 and 460.9, obtained by three independent methods, the number 457, as stated above, was employed in calculating the ionization of the *free benzylidenehydrazinodiacetic acid* at different concentrations.—W. A. FELSING.

isomeric diacid hydrazine, hydrazopropionic acid,  $\text{CH}_3\text{CH}(\text{COOH})\text{NH}-\text{NHCH}(\text{COOH})\text{CH}_3$ . As both hydrazinopropionic acid and benzylidenehydrazinopropionic acid are difficult to obtain, it is best to start with hydrazine hydrate, which we have found yields on treatment with  $\alpha$ -bromopropionic acid in alkaline solution the two diacid derivatives of hydrazine, hydrazinodipropionic acid and hydrazopropionic acid, and in addition hydrazinomonopropionic acid.

Above, attention has been called to the fact that Darapsky and Prabhakar interpreted the constitution of the reaction product of monobromomalonic acid on hydrazine as hydrazinodimalonic acid,  $\text{NH}_2\text{N}[\text{CH}(\text{CO}_2\text{H})_2]_2$ . They considered the possibility of this being hydrazomalonic acid but gave preference to the hydrazine formula for reasons given in the following quotation:

"Für obige Hydrazino-dimalonsäure kommen zwei Formeln in Betracht:

I.  $(\text{CO}_2\text{H})_2\text{CH} - \text{NH} - \text{NH} - \text{CH}(\text{CO}_2\text{H})_2$ . II.  $\text{NH}_2 - \text{N}[\text{CH}(\text{CO}_2\text{H})_2]_2$ .

Nach der symmetrischen Formel (I) enthält die Säure keine freie  $\text{NH}_2$ -Gruppe mehr und sollte sich darum nicht mit Benzaldehyd kondensieren. Indessen liefert auch die der asymmetrischen Formel (II) entsprechende und in analoger Weise entstehende Hydrazino-diessigsäure,  $\text{NH}_2 - \text{N}(\text{CH}_2\text{COOH})_2$ , von Curtius und Husson keine Benzalverbindung. Da ferner nach Harries und Haga auch bei der Einwirkung von Jodmethyl auf Hydrazinhydrat nur eine Amidogruppe in Reaktion tritt, und da in ähnlicher Weise nach Busch und Weiss aus Benzylchlorid und Hydrazinhydrat asymmetrisches Dibenzylhydrazin,  $\text{NH}_2\text{N}(\text{CH}_2\text{C}_6\text{H}_5)_2$  entsteht, dürfte auch obiger Hydrazinodimalonsäure die asymmetrische Formel (II) zukommen. Das schwer lösliche Bis-diammoniumsalz der Säure wäre sonach folgendermassen zu formulieren:  $2\text{N}_2\text{H}_4\text{NH}_2 - \text{N}[\text{CH}(\text{COOH})_2]_2$ ."

Attention might be called to the fact M. Busch has shown that ethyl chloroacetate reacts with phenylhydrazine to produce both symmetrical and unsymmetrical ethyl phenylhydrazinoacetate:

"Der Essigesterest vermag unter den gleichen Bedingungen sowohl an den  $\alpha$ -wie  $\beta$ -Stickstoff des Hydrazins zu treten; es entstehen beide Hydrazinoessigester neben einander, und zwar vorwiegend die asymmetrischen Verbindung." It is true, however, that free chloroacetic acid with phenylhydrazine produces "ausschliesslich die asymm.-Phenylhydrazinoessigsäure."<sup>1</sup>

Darapsky and Prabhakar claim that hydrazinodimalonic acid will not condense with aldehydes, but do not consider this an argument against the hydrazine nature of their malonic acid derivative, because of the supposed resistance of hydrazinodiacetic acid toward condensation with aldehydes. If their substance in reality be hydrazinodimalonic acid, it is probable that in alkaline solution with benzaldehyde it will condense normally and thus furnish an affirmative proof of its constitution. The isolation of hydrazopropionic acid, although in small amount, among the reaction products of monobromopropionic acid on hydrazine or hydrazinopropionic acid, along with the observation of Busch cited above, suggests

<sup>1</sup> Ber., 36, 3878 (1903).

the possibility that some  $\alpha$ -halogen acids may be found to react with hydrazine forming exclusively hydrazo compounds.

The wide divergence between the solubility in water of hydrazinodiacetic acid and the other hydrazino diacids thus far investigated suggests the possibility of hydrazinodiacetic acid being a polymer. An attempt by Mr. W. A. Felsing in this laboratory to determine the molecular weight of hydrazinodiacetic acid in aqueous solution by the boiling-point method led to the discovery of a peculiar decomposition of this substance, which proceeds with a vigorous evolution of prussic acid and carbon dioxide, when the boiling of the solution is effected by the platinum resistance method. Another product of the decomposition is ammonia. A tentative explanation of the mechanism of the reactions involved is evident from the following equations:

In the above experiment, after boiling produces no further evolution of prussic acid and all volatile products have been removed, the solution shows a strong reducing action toward permanganate. Furthermore, if the distillate obtained from the solution be passed over a heated copper oxide spiral, a test for formaldehyde can be obtained. These facts point to the formation of formic acid and methyl alcohol rather than their equivalent, acetic acid. It is contemplated to study this peculiar behavior of hydrazinodiacetic acid quantitatively and, if possible, synthesize the assumed intermediary product, methylhydroxylaminoacetic acid.

A second plausible explanation of the processes that go on in the disruption of the hydrazinodiacetic acid molecule under the catalytic action of platinum presents itself in the assumption of oximinoacetic acid,  $\text{HON} : \text{CHCOOH}$ , as an intermediary product. Hydroxylaminodiacetic acid could pass in this oxime by the elimination of a molecule of acetic acid or the equivalent of acetic acid plus water, formic acid and methyl alcohol.

Oximinoacetic acid was discovered by C. Cramer, who reports that the substance decomposes at  $120^\circ$  into  $\text{HCN}$ ,  $\text{CO}_2$ , and  $\text{H}_2\text{O}$  in aqueous solution.<sup>2</sup> Hantzsch and Wild's "oximidoessigacetsäure,"  $\text{COOHCH} : \text{NOCH}_2\text{COOH}$ , undergoes a similar decomposition into  $\text{HCN}$ ,  $\text{CO}_2$ , and  $\text{HOCH}_2\text{COOH}$ .<sup>3</sup> It will be interesting to determine whether platinum

<sup>1</sup> *J. prakt. Chem.*, 83, 256 (1911); *THIS JOURNAL*, 36, 1750 (1914).

<sup>2</sup> *Ber.*, 25, 715 (1892).

<sup>3</sup> *Ann.*, 289, 301 and 302 (1896).

will exert an accelerating influence in the decomposition of these oximes similar to its catalytic action on hydrazinodiacetic acid.

If the supposed hydrazinodimalonic acid of Darapsky and Prabhakar, be in reality a hydrazine, its solubility in water, along with the observation we have made in this respect on our three hydrazino diacids, indicates that the hydrazino diacids in the aliphatic series will prove to be hygroscopic substances, difficult to obtain in a form suitable for analysis.

#### Experimental Part.

**Benzylidenehydrazinodiacetic Acid**,  $C_6H_5CH = N - N(CH_2COOH)_2$ .—Hydrazinodiacetic acid is dissolved in two mols of 2 *N* potassium hydroxide and a little less than the calculated amount of benzaldehyde added. On vigorous shaking the aldehyde disappears and on adding the calculated amount of hydrochloric acid, the benzylidene compound, mixed with its acid potassium salt, immediately separates in the form of a copious white precipitate. The hydrazone acid is very soluble in alcohol, ether, and glacial acetic acid, slightly soluble in benzene and chloroform and practically insoluble in ligroin and petroleic ether. From benzene it crystallizes sparingly in the form of long, slender prisms. For analysis it can be purified by precipitation from an ether solution with petroleic ether. On being heated, the substance begins to soften at  $115^\circ$ , turning brown, and finally melts with gas evolution at  $123^\circ$ . The hydrazone readily dissolves in hot water with hydrolysis and, on steaming off the benzaldehyde, hydrazinodiacetic acid, melting with decomposition at  $176^\circ$ , crystallizes out. The lead, barium, and calcium salts of the benzylidene compound, prepared from a solution of the diammonium salt, were found to be difficultly soluble in water but were not further investigated.

Calc. for  $C_{11}H_{12}O_4N_2$ : C, 55.93%; H, 5.08%; N, 11.86%.

Found: C, 56.28; H, 5.25; N, 11.95.

**Monopotassium Benzylidenehydrazinodiacetate**.—The monopotassium salt of hydrazinodiacetic acid, as prepared above, can be separated from the admixed free hydrazone acid by extraction of the latter with ether. The salt, recrystallized from absolute alcohol, is obtained in characteristic aggregates of microscopic needles, which decompose on heating between  $210^\circ$  and  $215^\circ$ . The same salt is obtained by treating benzylidenehydrazinodiacetic acid in alcoholic solution with one mol of potassium hydroxide, or directly from monopotassium hydrazinodiacetate in concentrated aqueous solution by treatment with the calculated amount of benzaldehyde.

Calc. for  $C_{11}H_{11}O_4N_2K$ : C, 48.18%; H, 4.01%; N, 10.22%; K, 14.23%.

Found: C, 48.24; H, 4.11; N, 10.20, 10.26; K, 14.24, 14.21.

A normal condensation of benzaldehyde with *free* hydrazinodiacetic acid can also be readily effected with a practically quantitative yield as

follows: The hydrazine is dissolved in boiling water and to the hot solution one mol of benzaldehyde, emulsified in a little water, added. The solution is now vigorously shaken with cooling under a flowing hydrant. After a few minutes the hydrazone separates, free of admixture with the original hydrazine, and can be extracted with ether. On adding petroleic ether to the ether solution, the beautifully crystallizing benzylidenehydrazinodiacetic acid separates in radiating bunches of short needles.

**Monosodium Benzylidenehydrazinodiacetate.**—If benzylidenehydrazinodiacetic acid be dissolved in a little alcohol and one mol of 2 *N* sodium hydroxide added, the liquid solidifies after a few minutes. On recrystallization from alcohol the salt is obtained in microscopic, long, slender needles, which decompose at 338°. This salt is more difficultly soluble in alcohol than the corresponding potassium salt and contains one mol of water of crystallization. The same substance is obtained by treatment of a concentrated aqueous solution of monosodium hydrazinodiacetate with the calculated amount of benzaldehyde, when the addition of alcohol at the end of the reaction effects an almost quantitative precipitation of the hydrazone salt. For analysis it was found advisable to dry the salt at 70°, as on heating to a temperature sufficiently high to expel the water of crystallization, a slight decomposition results.

Calc. for  $C_{11}H_{11}O_4N_2Na \cdot H_2O$ : C, 47.83%; H, 4.71%; N, 10.14%; Na, 8.33%.

Found: C, 47.42; H, 4.76; N, 10.23; Na, 8.22, 8.34.

**Monopotassium *o*-Hydroxybenzylidenehydrazinodiacetate.**—Free hydrazinodiacetic acid condenses with salicylaldehyde, but the reaction proceeds more slowly than it does between the hydrazine and benzaldehyde. The hydroxybenzylidenehydrazone is obtained as an oil which on standing solidifies. However, no attempt was made to prepare it in a form suitable for analysis. The condensation of hydrazinodiacetic acid with salicylaldehyde is best effected by operating with the dipotassium salt of the former: the hydrazine acid is dissolved in two mols of 2 *N* KOH, one mol of salicylaldehyde added, and the solution allowed to stand one hour for completion of the reaction. The requisite amount of standard sulfuric acid to neutralize all the potassium is then added, because, if only the calculated amount of acid to liberate the monopotassium salt be used, it effects a very incomplete precipitation. The monopotassium salt, which separates in excellent yield from the acid solution, free as far as our observation goes from any admixed hydroxybenzylidenehydrazinodiacetic acid, is best purified by recrystallization from absolute alcohol. It is thus obtained with a faint yellow tinge in microscopic needles, which decompose at 212°. This hydrazone salt contains  $\frac{1}{2}$  mol of water of crystallization. For analysis it was dried at 75°, since it is not possible to eliminate the water without the substance undergoing a slight decomposition.

Calc. for  $C_{11}H_{11}O_3N_3K \cdot \frac{1}{2} H_2O$ : C, 44.15%; H, 4.01%; N, 9.36%, K, 13.04%.

Found: C, 44.16, 44.38; H, 4.24, 4.36; N, 9.54, 9.70, 9.31; K, 12.89, 12.85, 12.77.

**The Sodium Salt of Benzylidenehydrazinoacetic-propionic Acid from the Ethyl Ester of Nitrosiminoacetic-propionic Acid.**—10.6 g. (1 mol) of monochloroacetic acid in 50 cc. of water are treated with 22.75 g. potassium carbonate (0.5 mol). After effervescence ceases, 10 g. of alanine are added, the solution boiled for three hours under a return condenser, and then evaporated to dryness. In order to isolate the reaction product, 100 cc. of methyl alcohol are poured on the residue and esterification effected by passing hydrochloric acid gas through the boiling solution. After removal of the alcohol, the residue is dissolved in a little water and a slight excess of sodium nitrite added, whereupon the nitrosamine separates as a yellow oil in good yield. The reduction of the nitroso compound is effected in 50% alcoholic solution with 3% sodium amalgam. The amalgam, 200 g. for 8 g. of the nitrosamine, is added in small amounts with cooling. Twenty-four hours are required for the completion of the reduction. The solution is then boiled for half an hour to saponify the ester, concentrated to remove the alcohol, and finally shaken out with benzaldehyde. On acidifying, a good yield of the hydrazone, 6 g. from 8 g. of the nitrosamine, is obtained. For analysis the substance was recrystallized from glacial acetic acid and then from alcohol. From either solvent it separates in the form of characteristic rectangular, thin plates as seen under the microscope, which begin to turn brown at about  $220^\circ$  and decompose completely at  $330^\circ$ .

Calc. for  $C_{14}H_{17}O_3N_4Na$ : C, 55.17%; H, 5.17%; N, 10.73%; Na, 4.41%.

Found: C, 55.18; H, 5.18; N, 10.93; Na, 4.18.

Salicylaldehyde also reacts with this hydrazine forming a hydrazone which has an alkali content similar to the benzylidene compound. Recrystallized from alcohol it melts at  $222^\circ$ .

Calc. for  $C_{14}H_{17}O_3N_4Na$ : N, 10.11%; Na, 4.15%. Found: N, 10.23; Na, 4.10.

#### Hydrochloride of Iminoacetic-propionic Acid,

$HCl.HN \begin{cases} CH_2COOH \\ CH(CH_3)COOH \end{cases}$  .—The hydrochloride of iminoacetic-propionic acid is obtained by boiling the nitroso compound, described in the above preparation, for half an hour with an excess of dilute acid under a return condenser. The solution is next evaporated to dryness, the residue dissolved in alcohol, and the salt precipitated from the alcoholic solution with ether. It melts with decomposition at  $223^\circ$ .

Calc. for  $C_5H_9O_3NCl$ : N, 7.65%. Found: N, 7.66.

**The Potassium Salt of Benzylidenehydrazinoacetic-isobutyric Acid.**—To 24.7 g. of benzylidenehydrazinoisobutyric acid in 160 cc. of water, 32 g. of potassium carbonate are added with cooling and the solution

boiled two hours under a return condenser. Upon treatment of the solution with a slight excess of acetic acid, a mixture of the unchanged benzylidenehydrazinoacetic-isobutyric acid separates out. The former is removed from the precipitate by alcohol-ether treatment and the potassium salt recrystallized from alcohol. It is thus obtained in radiating bunches of long, slender prisms, which decompose at  $209^{\circ}$ .

Calc. for  $C_{22}H_{31}O_5N_4K$ : C, 55.12%; H, 5.48%; N, 9.89%; K, 6.89%.

Found: C, 54.78; H, 5.72; N, 9.84; K, 6.60.

**Benzylidenehydrazinoacetic-isobutyric Acid**,  $C_6H_5CH = N - N(CH_2COOH)(C(CH_3)_2COOH)$ .—Two grams of benzylidenehydrazino-isobutyric acid are suspended in a little water, 2.5 g. of monochloroacetic acid and 4.5 g. of potassium carbonate added, and the solution boiled half an hour under a return condenser. In order to convert all the potassium to sulfate, 4 cc. of concentrated sulfuric acid are added and the benzaldehyde steamed off. The solution is then made alkaline with ammonia, and the dissolved hydrazino acid reconverted to the benzylidene derivatives by treatment with the calculated amount of benzaldehyde. On acidifying the solution with glacial acetic acid the benzylidenehydrazinoacetic-isobutyric acid, mixed with the ether soluble benzylidenehydrazino-isobutyric acid, separates. As benzylidenehydrazinoacetic-isobutyric acid is exceptionally soluble in water, it is necessary to operate in concentrated solution. It is very sparingly soluble in ether, chloroform, and benzene, and recrystallizes from alcohol in a matted mass of short, slender needles, which melt at  $202^{\circ}$  with decomposition. The potassium salt of benzylidenehydrazinoacetic-isobutyric acid dissolves in KOH and is reprecipitated unchanged on acidifying. On the other hand, if it be dissolved in concentrated ammonia, sulfuric acid precipitates the alkali free hydrazone just described.

Calc. for  $C_{13}H_{16}O_4N_2$ : N, 10.61%. Found: N, 10.60.

**The Potassium Salt of Benzylidenehydrazinodipropionic Acid from Hydrazinopropionic Acid or from Benzylidenehydrazinopropionic Acid.**—A mixture of one mol of hydrazinopropionic acid, one mol of  $\alpha$ -bromopropionic acid, and two mols of potassium carbonate in 10 cc. of water for every gram of the hydrazinopropionic acid used is boiled two hours under a return condenser. The solution is then treated with one mol of benzaldehyde and, after the reaction is complete, the excess of aldehyde is extracted with ether. On acidifying the solution with hydrochloric acid, a mixture of the potassium salt of benzylidenehydrazinodipropionic acid and benzylidenehydrazinopropionic acid is obtained. The separation of these two substances is described further on under the action of  $\alpha$ -bromopropionic acid on hydrazine hydrate. In the action of bromopropionic acid on hydrazinopropionic acid, there is also formed a

small amount of hydrazopropionic acid, the isolation of which may be effected through the ethyl ester by the process described later.

The potassium salt of hydrazinodipropionic acid can also be obtained by the action of  $\alpha$ -bromopropionic acid on benzylidenehydrazinopropionic acid in potassium carbonate solution by employing the method used in the preparation of the potassium salt of benzylidenehydrazinoacetic-isobutyric acid from benzylidenehydrazinoisobutyric acid, described above.

**Action of Bromopropionic Acid on Hydrazine Hydrate.**—To a solution of 20 g. (2 mols) of bromopropionic acid in 20 cc. of water, 6 g. (1 mol) of hydrazine hydrate are added slowly from a dropping funnel with cooling 18 g. of solid potassium carbonate are next added with cooling and finally the solution warmed on the water bath as long as carbon dioxide is given off. The reaction is then completed by boiling for two hours under a return condenser. The solution is now shaken out with 12 cc. of benzaldehyde, ethered out in order to remove the excess of benzaldehyde, and finally neutralized with hydrochloric acid. A yellow oil, consisting of a mixture of benzylidenehydrazinopropionic acid and the potassium salt of benzylidenehydrazinodipropionic acid, separates and solidifies on stirring. The solution is filtered and the precipitate washed with water. To obtain the potassium salt of the benzylidenehydrazinodipropionic acid free from benzylidenehydrazinopropionic acid, the latter is extracted with ether. The potassium salt is then recrystallized from absolute alcohol in the form of thin plates, melting at  $210^{\circ}$  with decomposition. The three methods of preparation of monopotassium benzylidenehydrazinodipropionate, which have been described, yield products in every way identical.

Calc. for  $C_{20}H_{31}O_8N_2K$ : C, 55.12%; H, 5.48%; N, 9.89%; K, 6.89%.

Found: C, 54.81; H, 5.89; N, 10.01; K, 6.60.

To isolate the benzylidenehydrazinopropionic acid, the ether solution obtained above is shaken out with strong potassium hydroxide and the aqueous layer neutralized with HCl. The hydrazone separates in the form of a yellow oil which solidifies on stirring. Recrystallized from benzene, the substance is obtained colorless but turns slightly yellow on exposure to air. It is soluble in all common organic solvents with the exception of petroleic ether and melts with decomposition at  $106^{\circ}$ , as described by Traube and Longinescu.<sup>1</sup>

Calc. for  $C_{10}H_{15}O_2N_2$ : N, 14.58%. Found: N, 14.50.

If the crude benzylidenehydrazinopropionic acid, described above, be subjected to steam distillation, it dissolves only partially while a part separates as a smear. When the solution, filtered from the smear, is

<sup>1</sup> *Ber.*, 29, 672 (1907).

concentrated on a water bath and allowed to drop slowly into alcohol, the hydrazinopropionic acid separates in the form of a white granular powder. Purified by a second precipitation from water solution with alcohol, the hydrazine melts with decomposition at  $180^{\circ}$  and agrees in all its properties with the same preparation from ethyl semicarbazinopropionate.<sup>1</sup>

Calc. for  $C_5H_8O_2N_2$ : N, 26.92%. Found: N, 26.82.

The smear referred to above solidifies on cooling. In this impure state it melts at about  $90^{\circ}$  and decomposes at approximately  $105^{\circ}$ . It is soluble in all common organic solvents but insoluble in water, alkalies, and mineral acids. All attempts to crystallize the substance failed. An analysis of the crude material gave 14.47% nitrogen.

isolation of hydrazopropionic acid in small amount among the reaction products of potassium bromopropionate on hydrazine can be effected as follows: The filtrate, obtained above from the benzylidenehydrazinomon- and dipropionic acids, is evaporated to dryness and the residue esterified according to the method of Thiele and Bailey.<sup>2</sup> In this way a substance is obtained which was carefully compared with ethyl hydrazopropionate, prepared from hydrazopropionitrile, and the two preparations were found in every respect identical. However, as this substance, especially when impure, quickly changes to an oil, it has thus far not been possible to accumulate sufficient for an analysis. Our preparation melted at  $76^{\circ}$  to a clear liquid and a mixed sample of the two preparations gave the same result. From petroleic ether both preparations separated in the form of long prisms.

**Ethyl Semicarbazinodipropionate**,  $\text{NH}_2\text{CONHN}(\text{CH}(\text{CH}_3)\text{COOC}_2\text{H}_5)_2$ . —The potassium salt of benzylidenehydrazinodipropionic acid is suspended in water, a little dilute hydrochloric acid added, and the benzaldehyde removed by steam distillation. The solution is next evaporated *in vacuo* to dryness, the residue covered with saturated alcoholic HCl and this allowed to stand twelve hours. The alcohol is then distilled off *in vacuo*, the residue taken up with a little water and the solution treated with a slight excess of KCNO with cooling. At first an oil separates, probably some of the unchanged ester, and finally the ethyl semicarbazinodipropionate crystallizes out in poor yield. The ester is soluble in hot benzene, from which it separates on cooling, more difficultly soluble in hot ether, readily soluble in alcohol and chloroform, slightly soluble in cold water, and practically insoluble in petroleic ether. After recrystallization from

<sup>1</sup> *Ann.*, 303, 85 (1898).

<sup>2</sup> *Ibid.*, 303, 87 (1898).

benzene, the substance melts at  $159^{\circ}$  with decomposition. It reduces permanganate in sulfuric acid solution, giving an oxidation product which crystallizes beautifully from alcohol. This oxidation product, while it melts at the same temperature as the expected ethyl semicarbazinopyruvate,  $\text{NH}_2\text{CO} - \text{NHN} = \text{C}(\text{CH}_3)\text{COOC}_2\text{H}_5$ ,<sup>1</sup> and has the same solubilities, differs from it in crystalline form.<sup>2</sup> Our limited supply of material did not permit a further study of this compound to determine whether a case of stereoisomerism is involved.

Calc. for  $\text{C}_{11}\text{H}_{21}\text{O}_5\text{N}_3$ : C, 48.00%; H, 7.64%; N, 15.27%.

Found: C, 48.16; H, 7.83; N, 15.56.

Bailey and Read prepared semicarbazinodiacetic acid by the action of potassium chloroacetate on semicarbazide in alkaline solution and their work suggested the possibility of employing a similar process for the preparation of semicarbazinodipropionic acid. Prolonged heating of one mol of semicarbazide and three mols of bromopropionic acid in the presence of three mols of KOH in aqueous solution at a temperature of  $60^{\circ}$  was tried.<sup>3</sup> The isolation of the reaction products was carried out by the esterification process, employed by Bailey and Read in their preparation of semicarbazinomono- and diacetic acids. However, the propionic acid rest enters only once in the semicarbazide molecule under the conditions followed above. Here the ethylsemicarbazinopropionate obtained in poor yield, gave the correct melting point and proved identical with a sample of this substance in stock.

Calc. for  $\text{C}_8\text{H}_{13}\text{O}_3\text{N}_3$ : N, 24.10%. Found: N, 23.84.

**Methylbenzylideneaminohydantoic Acid**,  $\text{C}_6\text{H}_5\text{CH} = \text{N} - \text{N}(\text{CONH}_2) - \text{CH}(\text{CH}_3)\text{COOH}$ .—Two grams of benzylidenehydrazinopropionic acid, dissolved in 10 cc. of glacial acetic acid, are treated with 1 g. of finely powdered potassium cyanate, the solution allowed to stand two hours, and then the mixture diluted with water to eight times its volume. The hydantoic acid crystallizes out slowly, colored slightly yellow. It is difficultly soluble in all common organic solvents except alcohol, from which it crystallizes in radiating bunches of short, thick, diamond-shaped crystals, melting at  $180^{\circ}$ . The substance in dilute sulfuric acid solution readily splits off benzaldehyde, yielding a beautifully crystallizing compound, which is probably 5-methyl-1-aminohydantoin.

**THE NEUTRAL AMMONIUM SALTS OF SOME ORGANIC ACIDS  
AND THEIR SUBSTITUTED DERIVATIVES.**[SIXTH COMMUNICATION.<sup>1</sup>]

By LEROY MCMASTER AND A. C. MACILL.

Received May 18, 1916.

This work is a continuation of the work which has been in progress in this laboratory for several years on the preparation and investigation of the properties of the neutral ammonium salts of organic acids and their substituted derivatives. The salts previously studied were prepared by passing dry ammonia into solutions of the acids in the anhydrous solvents, methyl alcohol, ethyl alcohol, ether, acetone and benzene or in mixtures of some of these solvents. In this work we have made use of these same solvents, except methyl alcohol, and in addition we have used pure ethyl acetate. Naumann<sup>2</sup> found that a great many ammonium salts of organic acids are insoluble in ethyl acetate. Bateinan and Conrad<sup>3</sup> have recently found that the ammonium salts of some of the halogenoacetic acids are soluble in this reagent. In view of these facts, we thought it would be of interest to attempt to prepare some of the neutral ammonium salts in ethyl acetate. Several of the salts to be described were thus prepared. We have also tested the solubility of some of the ammonium salts in this solvent.

In the following work the neutral ammonium salts of tribromoacetic, phenylbromoacetic, *o*-nitrophenylacetic, phenylamidoacetic, glycolic,  $\alpha$ -bromopropionic,  $\beta$ -iodopropionic,  $\beta$ -chlorolactic, trichlorobutyric, caprylic, capric, lauric, myristic,  $\alpha$ -bromopalmitic,  $\alpha$ -bromostearic, acrylic,  $\beta$ -chlorocrotonic, erucic, dimethylmalonic, dipropylmalonic, isopropylmalonic, butylmalonic, allylmalonic, benzylmalonic, monobromosuccinic, dibromosuccinic, suberic and chlorofumaric acids have been prepared by passing dry ammonia into solutions of the respective organic acids in the above anhydrous solvents. A number of the properties of the salts were studied. The salts were quickly filtered by suction on alundum crucibles, washed with anhydrous ether, tested for neutrality, transferred to crystallizing dishes and placed for a short time in a vacuum desiccator.

The analysis of the salts consisted in determining the nitrogen by the Kjeldahl method. In all the salts except the phenylamidoacetate, the

<sup>3</sup> *THIS JOURNAL*, 37, 2553 (1915).

nitrogen present as "ammonium" nitrogen was determined, which is equal to the total nitrogen, except for the phenylamidoacetate and the *o*-nitrophenylacetate. In the case of these two salts, total nitrogen was also determined.

### The Substituted Acetic Acids.

**Ammonium Tribromoacetate.**—Schäffer<sup>1</sup> has prepared and investigated the properties of many of the salts of tribromoacetic acid, but did not prepare the ammonium salt. No reference to this salt can be found in the literature. When ammonia was passed into an ether solution of the acid the salt was precipitated as glistening white leaflets, soluble in water, methyl alcohol, ethyl alcohol and ethyl acetate. It is insoluble in ether, chloroform, acetone and benzene. A solution of the salt in water is neutral. The salt is not hygroscopic, and does not give off ammonia in dry or moist air. It decomposes rapidly, with evolution of ammonia, on heating to 50° and completely volatilizes below 100°.

This salt can also be prepared by saturating an alcoholic solution of the acid with ammonia and then adding an equal volume of ether. It has the same crystalline appearance as when it is prepared in ether alone.

Calc. for  $\text{CBr}_3\text{CO}_2(\text{NH}_4)$ : 4.96%. Found: 4.96% N.

There is a close resemblance in properties between ammonium tribromoacetate and ammonium monobromoacetate prepared by Bateman and Conrad.<sup>2</sup> Both salts crystallize in white leaflets from alcohol, and are soluble in water and ethyl acetate, and insoluble in benzene. The aqueous solution of the monobromo salt slowly hydrolyzes, while the solution of the tribromo salt does not hydrolyze. Neither salt is deliquescent and both are stable in the air. Both salts decompose on warming.

**Ammonium Phenylbromoacetate.**—There is no record of this salt having been prepared, even by the method of neutralization of an aqueous solution of the acid. It can be prepared in ether or ethyl alcohol. When prepared in ether it appears as a white amorphous powder, while it is formed as a crystalline compound in ethyl alcohol. The salt is somewhat hygroscopic and is very soluble in water. The solution, which is neutral at first, rapidly hydrolyzes. It decomposes rapidly in both dry and moist air, and when heated to 50° it decomposes very quickly, ammonia being evolved. The aqueous solution on being mixed with a solution of lead acetate slowly forms a white crystalline precipitate. The neutral ammonium salt is soluble in methyl alcohol, acetic acid and an excess of ethyl alcohol. It is very slightly soluble in acetone, and insoluble in ether and benzene.

Calc. for  $\text{C}_6\text{H}_5\text{CHBrCO}_2(\text{NH}_4)$ : 6.06%. Found: 6.02% N.

**Ammonium *o*-Nitrophenylacetate.**—No reference to this salt can be

<sup>1</sup> *Ber.*, 4, 371 (1871).

<sup>2</sup> *THIS JOURNAL*, 37, 2553 (1915).

found in the literature. It readily precipitates from an ether solution in the form of pale yellow crystals. On account of its solubility in ethyl alcohol, it cannot be prepared in this medium; but if an alcoholic ammonia solution of the acid is added to a large amount of ether, the ammonium salt separates in yellow crystals. This salt was also prepared in acetone and in ethyl acetate in the form of yellow crystals. It is only very slightly soluble in these reagents, but is very soluble in water, methyl and ethyl alcohols, and acetic acid. It is insoluble in benzene and chloroform. The salt is not deliquescent and does not become acid in an aqueous solution which stood for twenty-four hours. It is stable in dry and moist air. It does not decompose at  $50^{\circ}$  but loses ammonia slowly when heated to  $100^{\circ}$ .

Both the total and the ammonium nitrogen were determined in this salt, and analyses of the salt prepared in the different solvents proved that we had the neutral salt.

Calc. for  $C_8H_9NO_2CH_2CO_2(NH_4)$ : 7.07% ammonium N. Found: 7.04% (ether); 7.03% (ethyl alc.); 7.06% (acetone); 7.02% (ethyl acetate).

Calc. for  $C_8H_{10}N_2O_4$ : 14.14% total N. Found: 14.10% (ether); 14.05% (ethyl acetate).

**Ammonium Phenylamidoacetate.**—Phenylamidoacetic acid is insoluble in ethyl alcohol, ether, benzene, ethyl acetate and acetone, but is soluble in water. While our line of work is mainly to prepare the ammonium salts in anhydrous organic solvents, nevertheless we attempted to prepare this compound in aqueous solution since the free acid is insoluble in the above reagents. Furthermore, we could find no reference to the salt having been prepared.

An aqueous solution of the acid was saturated with ammonia and the solution was allowed to evaporate to dryness. Several attempts were made to prepare the neutral salt by this method, but we obtained an acid salt in each case. This was to be expected, as most of the ammonium salts of the organic acids, when thus prepared, are the acid salts and not the neutral salts. Attention has been called to this fact in the introductory statements of the previous papers<sup>1</sup> on this work.

The neutral ammonium salt of phenylamidoacetic acid, however, was prepared by treating an alcoholic suspension of the acid with dry ammonia. Under this condition, the acid gradually passed into solution. Ether was then added to this solution and there was precipitated a salt in the form of a pale greenish gray powder. It was filtered, washed and dried in the usual way. Although the free acid is odorless, the salt thus prepared has a slight odor which is very disagreeable.

The salt is very soluble in water and benzene. It is somewhat soluble in methyl alcohol, ethyl alcohol, ethyl acetate and acetic acid. It is very

<sup>1</sup> *Loc. cit.*

slightly soluble in acetone, and insoluble in ether and chloroform. The salt can be crystallized from benzene in splendid monoclinic crystals. The aqueous solution, which is neutral at first, slowly hydrolyzes and becomes acid. The salt does not lose ammonia in dry or moist air, but it is slightly deliquescent. When warmed to  $50^{\circ}$  the salt shows no evidence of decomposition, but at  $100^{\circ}$  ammonia is given off rapidly.

Calc. for  $C_4H_5CHNH_2CO_2(NH_4)$ : 16.67%. Found: 16.62% total N.

**Ammonium Glycolate.**—Heintz<sup>1</sup> mentions the acid ammonium salt of glycolic acid and states that it crystallizes as fine needles, which are easily soluble in water and hot alcohol. Ssabanejew<sup>2</sup> describes the preparation of a neutral solution of ammonium glycolate by treating a solution of glycolic acid with the calculated amount of ammonia. The experiment was carried out in a vacuum. On evaporation of the solution, there was obtained the acid salt in needle-like crystals. The literature contains no mention of the preparation of the neutral salt by precipitation.

On passing ammonia into a dilute solution of the acid in ethyl alcohol, a white precipitate of the ammonium salt at first appeared, which soon went into solution since this salt is quite soluble in alcohol. On continuing the addition of the ammonia, heat was developed and no further precipitate formed. The alcoholic solution was allowed to evaporate in the air and there was formed a syrupy liquid and some fan-like crystals. This experiment was repeated several times. The syrupy liquid was found to distil at but a few degrees below the boiling point of pure ethyl glycolate. The liquid was evidently a mixture of the ethyl ester of glycolic acid and ammonium salts of the acid.

Results similar to this have been previously noticed by one of us<sup>3</sup> and by Bateman and Conrad.<sup>4</sup> Heat favors the formation of the esters, and attention was called to the fact in a previous paper on this subject that, when the experiments are carried out in ethyl alcohol, it is necessary to keep the flasks surrounded by cold water, for, when the ammonia is passed into the solution of the acid in alcohol, heat is set free due to the action of the ammonia on the alcohol and also to the heat of neutralization. While in most of our experiments the precipitation flasks have been kept cold when the alcohols were used as solvents for the organic acids, in this case the flask was not kept cold. No doubt that in many of the cases, where the ammonium salts of even fairly strong acids were being prepared in the alcohols and the mixtures kept cold, small amounts of esters were formed. They were removed by the excess of alcohol and by the ether used to wash the salts while in the alundum crucible.

<sup>1</sup> *Jahresb. Fortschr. Chem.*, 1861, p. 446.

<sup>2</sup> *Chem. Zentr.*, II, 32 (1899).

<sup>3</sup> McMaster, *THIS JOURNAL*, 36, 1923 (1914).

<sup>4</sup> *Loc. cit.*

However, when a very concentrated alcoholic solution of the glycolic acid was used, the precipitate, which formed at first was not redissolved and very little ester was formed. The most of the acid was converted into the ammonium salt, and the limit of the solubility of this salt in the alcohol present was reached. The salt formed in small salt-like crystals. When recrystallized from alcohol, they appeared in the form of needles.

When dry ammonia was passed into a solution of the acid in acetone, much heat was evolved and a fine white precipitate formed, which almost immediately dissolved to form a brown solution. Owing to the heat evolved, we suspected the formation of some diacetoamine by the action of ammonia on the acetone vapor present. In order to determine whether this was true, we prepared some diacetoamine by passing ammonia and acetone vapor together through a tube heated to 100°. This is the method used by Heintz<sup>1</sup> to prepare diacetoamine. To the diacetoamine was added an acetone solution of glycolic acid. Fine, white crystals were formed which were insoluble in an excess of the diacetoamine. They were presumably a salt,<sup>2</sup> formed by the action of the basic amine on the acid. If the diacetoamine is saturated with ammonia before adding the acid, white crystals form but almost immediately redissolve and form a brown solution. If some dry, neutral ammonium glycolate (preparation of which will be described later) is added to diacetoamine, it readily dissolves and forms the brown solution. From these reactions we have concluded that the white crystals which formed when the ammonia was passed into an acetone solution of the acid and which dissolved almost at once to form a brown solution, consisted of the neutral ammonium salt, soluble in the diacetoamine produced during the experiment as a result of the action of ammonia gas on the vapor of the acetone and the mixture becoming hot. While neutral ammonium salts of the organic acids have been previously prepared in acetone by one<sup>3</sup> of us, the formation of diacetoamine has not been encountered. The reason for this is probably due to the fact that the solutions were kept cool during the passing in of the ammonia, or that the heat of reaction was not so great as in this case. In fact, we repeated the experiment and kept the acetone solution of the glycolic acid cold while passing in the ammonia. No diacetoamine was formed, but it was found necessary to agitate the cold acetone solution of the acid in an atmosphere of ammonia for several hours in order to obtain a yield of the ammonium salt. The salt separated out as fine, white crystals and analysis proved it to be the neutral ammonium salt.

When ammonia was passed into a solution of the acid in benzene, coarse, large crystals formed. Analysis of these crystals showed that they

<sup>1</sup> *Ann.*, 174, 133 (1874).

<sup>2</sup> Heintz, *Ibid.*, 198, 42 (1879); 203, 336 (1880).

<sup>3</sup> McMaster.

were a mixture of the acid salt and the neutral salt. No further attempt was made to prepare the neutral salt in benzene.

The neutral ammonium salt can be easily prepared in an ethyl acetate solution of the acid. It precipitated as fine, white crystals, very soluble in water. The aqueous solution gives a neutral reaction but soon becomes acid, due to hydrolysis. The salt is also very soluble in methyl alcohol, acetic acid and diacetoamine. It is slightly soluble in ethyl alcohol and ether, and insoluble in ethyl acetate, chloroform, benzene and acetone. It decomposes slowly in dry air and very rapidly in moist air, giving off ammonia. It is also slightly hygroscopic. On warming to 50°, decomposition of the salt took place rapidly, and at 100° the salt was completely decomposed into ammonia and the acid.

Calc. for  $\text{CH}_3\text{OHCO}_2(\text{NH}_4)$ : 15.05% N. Found: 15.03% (ethyl acetate); 15.01% (acetone).

**Comparison of Results.**—The ammonium salt of phenylacetic acid has been prepared and described in a previous paper by one of us.<sup>1</sup> A comparison of the salts of phenylacetic acid and its substituted derivatives shows many points of similarity. They can all be prepared in alcohol, although phenylamidoacetic acid is insoluble in this medium. The salts of *o*-nitrophenylacetic acid and phenylamidoacetic acid are yellowish in color. The others are white. They are all soluble in water and slightly soluble in acetone, but insoluble in ether and benzene. The phenylbromoacetate and phenylamidoacetate are slightly deliquescent, while the others are not deliquescent. The phenylacetate and phenylbromoacetate give off ammonia slowly in moist air. The others do not give off ammonia in the air.

Ammonium glycolate (hydroxyacetate) is quite unlike the salts of the other substituted acetic acids. It is insoluble in acetone and slightly soluble in ethyl alcohol and ether. It is also insoluble in ethyl acetate, benzene and chloroform. It loses ammonia very rapidly in moist air. Like the phenylbromoacetate and phenylamidoacetate, it is slightly hygroscopic.

#### The Substituted Propionic Acids.

**Ammonium  $\alpha$ -Bromopropionate.**—Weinig<sup>2</sup> has investigated the properties of many of the metallic salts of  $\alpha$ -bromopropionic acid but does not mention the ammonium salt. It can be easily prepared by treating an ether solution of the acid with ammonia. The heat of reaction is so great that, in order to prevent possible decomposition of the salt, the precipitation flask must be packed in ice. The salt separates out as a noncrystalline powder. The salt is quite soluble in ethyl alcohol, and, in order to prepare it in this medium, it is necessary to saturate the alcoholic solution of the acid with ammonia and pour it into a large amount of

<sup>1</sup> McMaster, *Loc. cit.*

<sup>2</sup> *Ann.*, 280, 248 (1894).

ether. Under these conditions, the salt forms as large, flaky crystals instead of an amorphous powder, as is the case when it is prepared in the ether direct. The salt is also very soluble in methyl alcohol, acetic acid and water. The neutral aqueous solution slowly becomes acid. The salt is slightly deliquescent. It is stable in dry air but loses its ammonia slowly in a moist atmosphere. It is insoluble in ethyl acetate, chloroform, acetone and benzene. It does not decompose at  $50^{\circ}$  in dry air, but at  $100^{\circ}$  ammonia is given off slowly.

Calc. for  $\text{CH}_3\text{CHBrCO}_2(\text{NH}_4)$ : 8.23%. Found: 8.21% N (ether); 8.21% N (ethyl alcohol).

**Ammonium  $\beta$ -Iodopropionate.**—The literature contains no account of this salt. By our method it formed in ether in frost-like crystals, which gradually became amorphous. It can also be precipitated in the crystalline condition from a concentrated solution of the acid in ethyl alcohol. The salt is slightly deliquescent and readily soluble in water, forming a neutral solution which slowly becomes acid. It is quite soluble in methyl and ethyl alcohols, acetic acid and acetone, slightly soluble in chloroform, ether and ethyl acetate. It is insoluble in benzene. Upon standing several months, the salt became brown due to liberated iodine. A rancid odor also developed.

The salt does not lose ammonia in dry air, but does so very slowly in moist air. At  $50^{\circ}$  there is no evidence of ammonia being given off, but at  $100^{\circ}$  the salt decomposes slowly.

Calc. for  $\text{CH}_2\text{ICH}_2\text{CO}_2(\text{NH}_4)$ : 6.45%. Found: 6.45% N.

**Ammonium  $\beta$ -Chlorolactate.**—This salt can be prepared from a solution of the acid in either ethyl alcohol or ether. In the alcohol, the salt forms as small, white crystals and, in the ether, as a granular powder. It is not deliquescent, is stable in dry air, and readily gives off ammonia in moist air. It gives off ammonia slowly at  $50^{\circ}$  and somewhat more rapidly at  $100^{\circ}$ .

The salt is very soluble in acetic acid and water. The neutral aqueous solution soon becomes acid. Silver nitrate gives a white precipitate when added to an aqueous solution of this salt. The precipitate is soluble in ammonium hydroxide. The salt is very slightly soluble in methyl alcohol and ethyl alcohol, and insoluble in ether, chloroform, acetone, benzene and ethyl acetate. No mention of this salt can be found in the literature, although many of the other salts of  $\beta$ -chloroacetic acid have been studied.

Calc. for  $\text{CH}_2\text{ClCH}(\text{OH})\text{CO}_2(\text{NH}_4)$ : 9.89% N. Found: 9.85% (ether); 9.87% (ethyl alc.).

**Comparison of Results.**—The neutral ammonium salts of propionic acid<sup>1</sup> and its substituted derivatives, thus far studied, can be prepared

<sup>1</sup> *Am. Chem. J.*, 49, 299 (1913).

in ether from which they separate as amorphous solids. The  $\beta$ -iodopropionate and  $\beta$ -chlorolactate can be precipitated as white crystals from concentrated alcoholic solutions of the acids. The  $\beta$ -chlorolactate is slightly soluble in ethyl and methyl alcohols. The other ammonium propionates are readily soluble in these solvents. All of them are very soluble in water and acetic acid, and insoluble in benzene. They are unstable in moist air, losing ammonia rapidly. The  $\beta$ -chlorolactate is not deliquescent, while the others are.

### Some Higher Fatty Acids, Including Several Substituted Derivatives.

**Ammonium Trichlorobutyrate.**—Garzarolli-Thurnlak<sup>1</sup> prepared this salt by treating an ether solution of the acid with solid ammonium carbonate. The ether was evaporated from this mixture by means of a stream of dry air. The salt was then extracted from the residue by means of more ether. It crystallized out of water partly in tuft-like and partly in quartz-like crystals. The salt was found to be more readily soluble in water and alcohol than in ether.

We prepared this salt in ether by our usual method. It formed as a white amorphous solid. It is very soluble in ethyl alcohol, and on this account, the yield is small if the ammonia is conducted even into a saturated alcoholic solution of the acid. It can be prepared also by passing ammonia into a saturated solution of the acid in acetone or ethyl acetate and then adding a large amount of ether. In each solvent the precipitate formed was crystalline. It dissolved readily in water, the solution remaining neutral for at least several days. The salt is also very soluble in methyl alcohol and appreciably so in ethyl acetate and acetone, and very slightly soluble in chloroform and ether. It is insoluble in benzene. It is not hygroscopic.

At ordinary temperatures the salt is stable in dry air, but at 50° ammonia is rapidly given off. Ammonia is given off slowly in moist air at room temperature. When heated to 100°, the salt decomposes into the acid and ammonia.

Calc. for  $C_3H_4Cl_3CO_2(NH_4)$ : 6.73% N. Found: 6.70% (ether).

Ammonium butyrate has been described in one of the papers previously referred to. Ammonium trichlorobutyrate undergoes decomposition into ammonia and the acid salt very slowly in the air, while ammonium butyrate does so very rapidly. The aqueous solution of the latter hydrolyzes very rapidly while that of the former does so very slowly. Both the butyrate and the trichlorobutyrate are easily precipitated from ether solutions of the acids, the first one in the form of granular crystals and the second one as an amorphous powder. Both are soluble in the alcohols, acetic acid and acetone. Ammonium isobutyrate, also described

<sup>1</sup> *Ann.*, 182, 185 (1876).

in a previous paper, precipitates from an ether solution of the acid as a lustrous white solid and differs from the butyrate and the trichlorobutyrate in that it has a very high vapor tension. The ammonium butyrate is deliquescent, while the isobutyrate and the trichlorobutyrate are not deliquescent. The ammonium isobutyrate resembles the other two as to solubility in the alcohols.

**Ammonium Caprylate.**—Currie<sup>1</sup> found that he could prepare this salt by passing dry ammonia into a benzene solution of the acid. He obtained needle-like crystals, which readily hydrolyzed in an aqueous solution, and which readily gave off the odor of caprylic acid when exposed to the air. No analysis of the salt was recorded by Currie. We have prepared the salt in ether. It dried to a cheese-like mass. It did not precipitate from ethyl alcohol, but when a mixture of equal parts of ether and alcohol were used, it precipitated as monoclinic crystals. An aqueous solution of the salt lathers freely on shaking. This solution, which is neutral at first, becomes acid on standing a very short time. The salt is slightly hygroscopic, loses ammonia very slowly in dry air and very rapidly in moist air. It is very soluble in acetic acid and ethyl alcohol, and slightly soluble in methyl alcohol. It is less soluble in acetone and ethyl acetate than in methyl alcohol. It is insoluble in chloroform, ether and benzene. Analysis of the salt dried at 50° showed that there had been some decomposition.

Calc. for  $C_7H_{14}CO_2(NH_4)$ : 8.70% N. Found: 8.68% (ether); 8.64% (alcohol-ether mixt.).

After standing some weeks, the above salt became yellowish in color and developed the odor of caprylic acid.

**Ammonium Caprate.**—Currie<sup>2</sup> also describes the preparation of this salt in benzene and found that its properties are the same as those of ammonium caprylate. The salt can also be prepared in ether as a fine, white, amorphous substance, which is greasy to the touch. By conducting ammonia into a saturated alcoholic solution of the acid and then adding an excess of ether, the neutral salt precipitates as fine, white crystals. It dissolves readily in water, to which it imparts a neutral reaction. The solution quickly hydrolyzes. The salt is slightly hygroscopic. It is insoluble in benzene, slightly soluble in acetone and ether, and readily soluble in methyl alcohol, ethyl alcohol and acetic acid. It gives off ammonia slowly in dry air and rapidly in moist air. At 50° the evolution of ammonia is very rapid and is complete before the temperature reaches 100°.

Calc. for  $C_9H_{18}CO_2(NH_4)$ : 7.41% N. Found: 7.41% N.

**Ammonium Laurate.**—Many of the salts of lauric acid have been pre-

<sup>1</sup> *J. Agr. Research*, 2, 8 (1914).

<sup>2</sup> *Loc. cit.*

pared by Oudemans,<sup>1</sup> who prepared the acid ammonium salt by neutralizing an aqueous solution of the acid with ammonium hydroxide, and evaporating to crystallization.

When the dry ammonia was passed into an ether solution of the acid, there was formed a curdy, white precipitate which soon changed to one flaky in appearance. It was also prepared by adding ether to an alcoholic ammonia solution of the acid. In this case, fine, white crystals formed. The salt is very soluble in water. This aqueous solution remains neutral for at least two days. It also lathers very freely when shaken. The salt is soluble in methyl and ethyl alcohols and acetic acid, slightly soluble in acetone, and insoluble in chloroform, ether and benzene. The salt is deliquescent. It does not lose ammonia in exposure to dry or moist air. It gives off ammonia slowly at 50° and decomposes very rapidly at 100°.

Calc. for  $C_{11}H_{23}CO_2(NH_4)$ : 6.45% N. Found: 6.44% (ether); 6.43% (ether-alc. mixt.).

**Ammonium Myristate.**—No record can be found of the preparation of this salt. It can be prepared by passing dry ammonia into an ether solution of myristic acid. On passing in the gas, there was formed a fine, white, noncrystalline precipitate. By dissolving this precipitate in ethyl alcohol and evaporating the solvent, the salt was obtained in the crystalline form. It is easily soluble in water, the solution remaining neutral at the end of two days. It is readily soluble in ethyl alcohol, methyl alcohol and acetic acid, and insoluble in ether, benzene, acetone and chloroform. It is not hygroscopic. At ordinary temperatures there is no evidence of decomposition in dry air, but it decomposes slowly at 50° and is completely decomposed at the temperature of boiling water. It decomposes very slowly in moist air.

Calc. for  $C_{18}H_{37}CO_2(NH_4)$ : 5.71%. Found: 5.70% N.

**Ammonium  $\alpha$ -Bromopalmitate.**—We could find no record of the preparation of this salt. When prepared by passing ammonia into an ether solution of the acid, it precipitated first as a gelatinous mass, which soon changed to an amorphous powder. It could not be precipitated in alcohol, owing to its solubility in that solvent; but when a saturated alcoholic solution of the acid, into which ammonia had been passed for some time, was poured into a rather large volume of ether, the salt formed in fine, frost-like crystals.

The salt dissolves easily in water. The solution lathers copiously on shaking. We have here another example of an ammonium soap. This is true of the ammonium salts of all the higher fatty acids, such as capric acid, caprylic acid, myristic acid, etc. The neutral aqueous solution hydrolyzes very slowly. The salt is very soluble in acetic acid, methyl

<sup>1</sup> *Jahresb. Fortschr. Chem.*, 1863, p. 331.

alcohol and ethyl alcohol. When the ethyl alcohol solution of the salt is warmed, there is some decomposition of the salt and an ester is formed. The salt is insoluble in ether, benzene and chloroform, and slightly soluble in acetone. It loses ammonia very slowly in dry air and rapidly in moist air. It gives off but little ammonia at 50°, but decomposition takes place rapidly at 100°. The salt is not hygroscopic.

Calc. for  $C_{15}H_{31}BrCO_2(NH_4)$ : 3.99% N. Found: 3.95% (ether); 3.95% (ether-alc. mixt.).

Ammonium palmitate, described in a previous paper by McMaster,<sup>1</sup> and ammonium bromopalmitate can both be prepared in ether. The first is soluble in acetone, while the second is only slightly soluble. Both are soluble in water, methyl alcohol and ethyl alcohol. Both lather very freely in water, indicating ammonium soaps. The aqueous solution of the palmitate hydrolyzes much more rapidly than that of the bromopalmitate. The latter decomposes in the air more slowly than the first. Neither salt is hygroscopic.

**Ammonium  $\alpha$ -Bromostearate.**—As in the case of the corresponding bromopalmitate, no record of this salt can be found in the literature. It was prepared in ether as a noncrystalline compound. It was also precipitated from an alcoholic ammonia solution of the acid upon the addition of ether. In this case it formed small, white crystals. The aqueous solution lathers freely on shaking and very slowly becomes acid. The salt is not deliquescent. It is stable in dry air but loses ammonia in moist air. It is soluble in methyl and ethyl alcohols, slightly soluble in cold acetone and readily soluble in hot acetone. It does not dissolve in ether, ethyl acetate, benzene or chloroform. When treated with acetic acid,  $\alpha$ -bromostearic acid is formed. The salt decomposes slowly with the liberation of ammonia both at 50° and 100°.

Calc. for  $C_{17}H_{33}BrCO_2(NH_4)$ : 3.69%. Found: 3.66% N.

The neutral ammonium salt of  $\alpha$ -bromostearic acid can thus be prepared in ether as well as the neutral salt of stearic acid. The preparation and properties of this latter salt have been previously described by McMaster. Both salts are soluble in water, methyl alcohol, ethyl alcohol and acetone. In the last solvent the bromostearate is less soluble than the stearate. Both salts are not hygroscopic, do not lose ammonia in dry air, but do in moist air.

**Comparison of Results.**—Including those neutral-ammonium salts described in the previous papers, there have thus far been prepared and studied twenty-two salts of the saturated monobasic acids of the aliphatic series, or derivatives of acids of that series. We have found that there is a very wide variation in many of their properties. There seems to be no uniformity in their action when exposed to the air. Some of

<sup>1</sup> *Loc. cit.*

them do not deliquesce, some do so very slowly, and some very rapidly. Some of these salts lose ammonia in the air with varying degrees of rapidity, while others of them do not lose ammonia. Most of these salts hydrolyze, but not all of them. They all have the general property of being soluble in water and more or less so in the alcohols. Most of them are slightly soluble in acetone. All are insoluble in benzene and ether. A few of them have also been found to be insoluble in ethyl acetate.

#### Some Monobasic Unsaturated Acids.

**Ammonium Acrylate.**—When dry ammonia was passed into an ether solution of acrylic acid, a gelatinous mass was formed. This condition did not change when the substance was dried in an atmosphere of ammonia. This same gelatinous, glue-like mass was formed also in an alcoholic solution of the acid, even when the solution was packed in ice. We also attempted to prepare the salt in acetone. On passing in the ammonia, there was formed at first a white precipitate, which very soon redissolved and formed a light brown solution. The heat of reaction was sufficient to raise the temperature almost to the boiling point of the acetone. No doubt there was formed here again some diacetoamine in which the salt, which first formed, was redissolved. The results in this case were the same as we had in the case of the glycolic acid.

The neutral ammonium acrylate was finally prepared by passing the ammonia into a benzene solution of the acid and evaporating off the benzene. Monoclinic crystals were obtained. If a solution of the acid in ethyl acetate be used, the salt separates as a fine, granular mass. The salt, prepared in either medium, is not hygroscopic, does not lose ammonia when exposed to dry or moist air, and does not decompose when warmed to 100°. After standing several months, the salt developed the odor of acrylic acid. An aqueous solution of the salt slowly hydrolyzes.

The salt is soluble in water and acetic acid, slightly soluble in methyl and ethyl alcohols, and insoluble in ether, chloroform, ethyl acetate, acetone and benzene. No previous record of this salt could be found.

Calc. for  $\text{CH}_2\text{CHCO}_2(\text{NH}_4)$ : 15.73%. Found: 15.69% N (benzene). Prepared in ethyl acetate. Found: 15.70% N.

**Ammonium  $\beta$ -Chlorocrotonate.**—Sarnow<sup>1</sup> prepared the ammonium salt of the  $\alpha$ -acid by treating the acid with a saturated solution of ammonium carbonate. He found that the salt crystallized out from the solution in plate-like crystals, which sublimed at 100°. No mention is made of the ammonium salt of the  $\beta$ -acid.

When prepared by our method, the salt of the  $\beta$ -acid was precipitated from an ether solution as small, flaky crystals. The salt is very soluble in ethyl alcohol, but can be prepared by pouring a saturated, alcoholic ammonia solution of the acid into ether. It here separates out as a fine,

<sup>1</sup> *Ann.*, 164, 99 (1872).

white, crystalline mass. The salt was also precipitated as fine crystals in acetone.

The salt is not hygroscopic. It is very soluble in water and forms a neutral solution, which soon hydrolyzes. The salt is stable in dry air, but loses ammonia slowly in moist air. The salt is also very soluble in methyl alcohol and acetic acid as well as in ethyl alcohol. It is only slightly soluble in acetone and ethyl acetate. It is insoluble in ether, chloroform and benzene. It can be dried at  $100^{\circ}$  without decomposition.

Calc. for  $C_3H_5ClCO_2(NH_4)$ : 10.18% N. Found: 10.14% (ether); 10.19% (acetone); 10.15% (ether-alc. mixt.).

Ammonium crotonate has been described by McMaster. It was prepared, as we have prepared the  $\beta$ -chlorocrotonate, in ether and in a saturated alcoholic solution of the acid. In the case of the  $\beta$ -chlorocrotonate, it was necessary to add ether to the alcoholic ammonia solution before precipitation took place. Both salts separate from ethyl alcohol in a crystalline condition, and both are readily soluble in water. The aqueous solution in each case quickly hydrolyzes. Both salts are also soluble in methyl alcohol and acetic acid, and insoluble in chloroform and ether. Neither salt is deliquescent.

**Ammonium Erucate.**—A cream-colored, amorphous precipitate of this salt formed when ammonia was passed into the ether solution of the acid. Erucic acid is only slightly soluble in ethyl alcohol, and we thus obtained a small yield of white crystals in this solvent. The solution of the salt in water also lathers freely on shaking. The aqueous solution, neutral at first, hydrolyzes. The salt does not lose ammonia in dry air, but does so very slowly in moist air. It is not hygroscopic and can be dried at  $100^{\circ}$  without decomposition.

The salt is very slightly soluble in ethyl alcohol and somewhat more soluble in methyl alcohol. It crystallizes from the latter in monoclinic crystals. The salt is sparingly soluble in acetone and insoluble in ether, ethyl acetate and benzene. It is readily soluble in acetic acid.

Calc. for  $C_{21}H_{41}CO_2(NH_4)$ : 3.94% N. Found: 3.91% (ether); 3.95% (ethyl alc.).

The literature makes no mention of this salt so far as we can find.

**Comparison of Results.**—The neutral ammonium salts of crotonic, oleic, and elaidic acids have been described by McMaster in previous papers. With the exception of ammonium acrylate, the salts of the unsaturated monobasic acids can be prepared in ether, from which they separate in gelatinous masses, which gradually change over to amorphous solids. Ammonium oleate can be prepared in a crystalline form if ammonia is passed in for a sufficient length of time. The acrylate can be prepared in ethyl acetate. These salts are all soluble in ethyl alcohol, methyl alcohol and water. They all separate from an alcoholic solution

on evaporation as fine, white crystals. Their aqueous solutions hydrolyze. They are not deliquescent.

### The Substituted Malonic Acids.

**Ammonium Dimethylmalonate.**—There is no mention in the literature of the neutral ammonium salts of the substituted malonic acids included in this investigation. Ammonium dimethylmalonate can be prepared from a solution of the acid in ether or ethyl alcohol by our method. In ether, it is precipitated as a curdy mass, which, on washing and drying, becomes a white, amorphous powder. In alcohol, it is precipitated as crystals.

The salt forms a neutral solution in water and soon hydrolyzes. The salt is very deliquescent, and gives off ammonia slowly in dry air and very rapidly in moist air. It decomposes into ammonia and the acid when heated to 50°. The salt is readily soluble in methyl alcohol and acetic acid, slightly soluble in ethyl alcohol and ethyl acetate, and insoluble in ether, benzene, chloroform and acetone.

The neutral salt can also be prepared in ethyl acetate and acetone. From each of these solvents it readily precipitates in a crystalline form.

Calc. for  $(\text{CH}_3)_2\text{C}(\text{CO}_2\text{NH}_4)_2$ : 16.87% N. Found: 16.80% (ether); 16.79% (ethyl alc.); 16.81% (ethyl acetate); 16.85% (acetone).

**Ammonium Dipropylmalonate.**—This salt was prepared from solutions of the acid in ether, ethyl alcohol, ethyl acetate and acetone. From ether, it was precipitated as a gelatinous mass which changed to hard lumps. These lumps were crushed, washed and dried. From solutions of the acid in ethyl alcohol, ethyl acetate and acetone, the neutral salt precipitated as white, monoclinic crystals. It was necessary to surround the ethyl alcohol solution with ice to prevent the formation of an ester. The salt formed a solution in water which remained neutral for at least several days. It is slightly deliquescent. It does not give off ammonia in dry or moist air. There is no decomposition at 50°, but at 100° ammonia is slowly evolved.

The salt is readily soluble in acetic acid and methyl alcohol. It is slightly soluble in ethyl alcohol and ethyl acetate, and insoluble in ether, acetone, chloroform and benzene.

Calc. for  $(\text{C}_3\text{H}_7)_2\text{C}(\text{CO}_2\text{NH}_4)_2$ : 12.61% N. Found: 12.59% (ether); 12.58% (ethyl alc.); 12.56% (ethyl acetate); 12.62% (acetone).

**Ammonium Isopropylmalonate.**—On addition of dry ammonia to an ether solution of the acid, this salt formed as a mucilaginous precipitate which, on drying, collected in hard lumps. From ethyl alcohol, it precipitated as white crystals.

The salt is very deliquescent, and on exposure to moist air breaks up into ammonia and the acid. It is stable in dry air at ordinary tempera-

tures. At 50° it gives off ammonia slowly. At 100° the decomposition is somewhat more rapid.

An aqueous solution of the salt remains neutral to litmus. The salt is very soluble in methyl alcohol and acetic acid. It is very slightly soluble in ethyl alcohol and benzene, and insoluble in acetone, ethyl acetate and chloroform.

Calc. for  $C_5H_7CH(CO_2NH_4)_2$ : 15.55% N. Found: 15.52% (ether); 15.50% (ethyl alc.).

**Ammonium Butylmalonate.**—From a solution of the acid in ether this salt precipitated in asbestos-like fibers, which dried to a hard mass. From ethyl alcohol it precipitated as rhombic crystals. In order to prevent the formation of some ester, it was necessary to keep the alcohol solution packed in ice.

The salt is slightly deliquescent, and readily dissolves in water to form a neutral solution, which soon becomes acid to sensitive litmus. The salt is stable in dry air at room temperature, but at 50° ammonia is slowly evolved. It loses ammonia rapidly in moist air or when heated to 100°. The salt is very soluble in methyl alcohol and acetic acid, slightly soluble in ethyl acetate, and insoluble in ethyl alcohol, ether, acetone, chloroform and benzene.

Calc. for  $C_5H_9CH(CO_2NH_4)_2$ : 14.45% N. Found: 14.40% (ether); 14.40% (ethyl alc.).

**Ammonium Allylmalonate.**—Dry ammonia precipitated this salt as a fibrous mass from an ether solution of the acid. On drying this precipitate it formed as hard lumps. It formed as a white, crystalline compound of an ethyl alcohol solution of the acid. The heat of neutralization in the ethyl alcohol was sufficient to form some ester unless the solution was packed in ice. The salt was also prepared in acetone. The crystals resembled those formed in the alcohol.

The salt is very deliquescent, and loses ammonia rapidly in both dry and moist air. It is difficult to prevent decomposition of the salt, even during the drying of it. It decomposes very rapidly at 50°, and before 100° is reached, the salt loses all its ammonia.

The aqueous solution of the salt, which is at first neutral, hydrolyzes on standing. The salt is readily soluble in methyl alcohol and acetic acid, very slightly soluble in ethyl alcohol, ethyl acetate and acetone, and insoluble in chloroform, ether and benzene.

Calc. for  $C_5H_7CH(CO_2NH_4)_2$ : 15.73% N. Found: 15.74% (ether); 15.70% (ethyl alc.); 15.70% (acetone).

**Ammonium Benzylmalonate.**—This salt readily precipitated in a non-crystalline condition from a solution of the acid in ether. It precipitated as hexagonal crystals from a solution of the acid in ethyl alcohol. Neither the crystalline nor the noncrystalline form was hygroscopic.

The salt does not lose ammonia in dry or moist air even at 50°, but an

analysis of a sample kept at  $100^{\circ}$  for ten minutes showed that some decomposition had taken place. The salt dissolved readily in water, to which it imparted a neutral reaction. This solution remained neutral at least twenty-four hours. The salt is also very soluble in acetic acid and methyl alcohol, but only sparingly so in ethyl alcohol, ethyl acetate and chloroform. It is insoluble in ether, acetone and benzene.

Calc. for  $C_4H_5CH(CO_2NH_4)_2$ : 13.08% N. Found: 13.05% (ether); 13.04% (ethyl alc.).

**Comparison of Results.**—Previous papers by one of us<sup>1</sup> have given an account of the preparation and properties of the neutral ammonium salts of malonic acid and ethyl malonic acid. We have just described the neutral ammonium salts of six other substituted derivatives of malonic acid. All of these salts precipitate in ether as amorphous compounds, and as fine, white crystals in ethyl alcohol. They are all very soluble in water and insoluble in ether and benzene. With the exception of the allyl compound, all are insoluble in acetone. Most of them lose ammonia in moist air. The aqueous solutions of the salts of dimethyl, butyl and allylmalonic acids hydrolyze. The aqueous solutions of the others do not hydrolyze. The salts of malonic and benzylmalonic acids do not deliquesce, while all the others do. The most striking characteristics common to all these malonates is their solubility in the common alcohols. All of them are soluble in methyl alcohol and, with the exception of the butylmalonate, all are only very slightly soluble in ethyl alcohol. The butylmalonate is insoluble in this solvent.

#### The Substituted Succinic Acids.

**Ammonium Monobromosuccinate.**—Meyer and Jacobson state, in their *Lehrbuch der Organischen Chemie*, that when monobromosuccinic acid is treated with a methyl alcohol solution of ammonia the  $\beta$ -monoamide of malic acid results. The exact conditions are not given. No mention is made of the neutral ammonium salt.

When an ether solution of the acid was treated with dry ammonia, a fibrous precipitate formed which soon changed to an amorphous powder. When an alcoholic solution of the acid was used, a crystalline precipitate formed. The salt was found to be not deliquescent, and stable in moist as well as in dry air. The salt did not decompose when heated to  $50^{\circ}$ , but at  $100^{\circ}$  there was a slight decomposition.

The salt is very soluble in water and acetic acid. The aqueous solution remained neutral for several days. The salt is slightly soluble in ethyl alcohol and much less so in methyl alcohol. It is also very sparingly soluble in ethyl acetate and chloroform, and insoluble in ether, acetone and benzene. An aqueous solution of the salt gave with silver nitrate solution a white precipitate, insoluble in dilute nitric acid. With ferric

<sup>1</sup> McMaster, *Loc. cit.*

chloride solution, a yellowish brown precipitate formed, but with lead acetate solution no precipitate was formed.

Calc. for  $C_2H_2Br(CO_2NH_4)_2$ : 12.12% N. Found: 12.12% (ether); 12.10% (ethyl alc.).

**Ammonium Dibromosuccinate.**—Kekulé<sup>1</sup> prepared ammonium dibromosuccinate from an aqueous solution of the acid and found that it crystallized out of water without water of crystallization.

When ammonia was passed into an ethyl alcohol solution of the acid, the neutral salt formed as a fine, white, granular precipitate. In an ether solution, the salt first formed as a gelatinous mass, which changed to a crystalline powder. The salt is not hygroscopic. A solution of the salt in water is neutral at first but becomes slowly acid on standing. The aqueous solution gave with silver nitrate solution a white precipitate, soluble in dilute nitric acid. It also gave a yellowish brown precipitate with ferric chloride solution.

The salt is somewhat soluble in methyl alcohol. It is less soluble in ethyl alcohol than in methyl alcohol. It is soluble in acetic acid, and insoluble in ether, chloroform, ethyl acetate, acetone and benzene. The salt is stable in dry air but loses ammonia in moist air. It decomposes slowly with the evolution of ammonia at 50°. At 100° there is a rapid decomposition.

Calc. for  $C_2H_2Br_2(CO_2NH_4)_2$ : 9.03% N. Found: 9.00% (ether).

**Comparison of Results.**—Ammonium succinate has been described by McMaster. The neutral ammonium salts of succinic acid and its substituted bromo derivatives can be prepared in an ether or ethyl alcohol solution of the acids. In ether, the salts separate in an amorphous condition, and in ethyl alcohol in a crystalline form. All of them are easily soluble in water. The aqueous solution of the ammonium dibromosuccinate hydrolyzes very slowly. All of the salts described are only slightly soluble in ethyl alcohol. The salts of the bromo derivatives are insoluble in acetone, ether and benzene. All three salts are stable in dry air, and none of them deliquesce.

### Suberic Acid.

**Ammonium Suberate.**—Gantter and Hell<sup>2</sup> prepared the neutral ammonium salt of suberic acid by evaporating an ammoniacal solution of the acid in an atmosphere of ammonia and over potassium hydroxide. They obtained the salt in well-defined leaflets, which completely decomposed at 110° into ammonia and the acid.

The salt could not be prepared in ether on account of the insolubility of the acid in that medium. When dry ammonia was passed into an ethyl alcohol solution of the acid, no precipitate formed. Ether was then added to this alcoholic ammonia solution of the acid, whereupon fine,

<sup>1</sup> *Ann. Spl.*, 1, 354 (1862).

<sup>2</sup> *Ber.*, 13, 1166 (1880).

white crystals of neutral ammonium suberate formed. A white, crystalline precipitate of the salt also formed immediately when the ammonia was passed into an ethyl acetate solution of the acid.

The salt is soluble in water and methyl alcohol, slightly soluble in acetic acid, ethyl alcohol and benzene, and insoluble in acetone, chloroform and ethyl acetate. The aqueous solution of the salt does not hydrolyze.

The salt is not hygroscopic. At ordinary temperatures it does not lose ammonia in dry or moist air. At 50° it loses ammonia slowly, and at 100° the decomposition is very rapid. At 100° all the ammonia has been liberated and analysis shows that only the acid remains.

Calc. for  $C_8H_{12}(CO_2NH_4)_2$ : 13.46% N. Found: 13.40% (ether-alc. mixt.); 13.46% (ethyl acetate); 13.44% (benzene).

### Comparison of the Ammonium Salts of the Saturated Dibasic Acids.—

We have described in this and previous papers the preparation and properties of the neutral ammonium salts of sixteen saturated dibasic acids, or substituted derivatives of them, not including the hydroxy derivatives. While there is a rather wide variation in their general properties, they have many points of similarity. All of them can be prepared in ether, and in every case they separate as amorphous compounds. With the exception of ammonium pimelate, all of them readily precipitate in a crystalline condition from an alcoholic solution of the acid. In those salts having both carboxyl groups attached to the same carbon atom there appears to be a strong tendency to deliquesce. With the exception of the pimelate, those salts, which have the carboxyl groups attached to different carbon atoms, do not deliquesce. The aqueous solutions of the salts of the dibasic acids either do not hydrolyze at all or hydrolyze only very slowly. None of them give off ammonia in dry air, except the pimelate. Some of them give off ammonia very slowly in moist air. Unlike the salts of the saturated monobasic acids, all of them, except the pimelate, are only very slightly soluble in ethyl alcohol. The ammonium pimelate thus has different properties in general from the other saturated dibasic acids.

### Chlorofumaric Acid.

**Ammonium Chlorofumarate.**—Perkins<sup>1</sup> prepared this salt by allowing the acid to stand in an atmosphere of ammonia. He states that combination takes place with energy and that, if an excess of ammonia be left with the salt, there is no decomposition with removal of the chlorine. Perkins also states that, on slowly evaporating an aqueous solution of the salt, beautiful transparent crystals of the salt separate, which are moderately soluble in water and can be dried at 100° without decomposition. Mushman<sup>2</sup> found these crystals to be monoclinic.

<sup>1</sup> *J. Chem. Soc.*, 53, 699 (1888).

<sup>2</sup> *Ibid.*

By our method this salt was prepared in an ether solution of the acid. On first passing in the ammonia, a colloidal precipitate formed which passed to a gelatinous mass and then finally to a fine, white powder. In a saturated alcoholic solution of the acid, a fine, flaky, crystalline precipitate formed at once. In each case the neutral salt was formed. It is not deliquescent, and gives off ammonia very slowly in moist air. It is readily soluble in water, yielding a neutral solution which does not hydrolyze.

The salt is also soluble in acetic acid. It is very slightly soluble in methyl and ethyl alcohols, and insoluble in acetone, chloroform, ether, ethyl acetate and benzene. It can be heated to  $100^{\circ}$  without decomposition.

Calc. for  $C_2HCl(CO_2NH_4)_2$ : 15.17% N. Found: 15.14% (ether); 15.12% (ethyl alc.).

This salt has properties similar to ammonium fumarate previously prepared in this laboratory. Both salts readily precipitate from ethyl alcohol, the fumarate as an amorphous powder and the chlorofumarate as fine crystals. Both salts are very slightly soluble in ethyl alcohol, and neither salt deliquesces. Both salts are soluble in water forming neutral solutions, which do not hydrolyze.

This investigation is being continued with other organic acids and their substituted derivatives.

St. Louis, Mo.

## THE ACTION OF A SOLUTION OF POTASSIUM HYDROXIDE IN ALCOHOL ON OXALIC ESTERS.

By N. C. QUA AND D. McLAREN.

Received June 15, 1916.

One method of preparing the monoalkyl esters of dibasic acids is by the treatment of the dialkyl esters with the calculated amount of the alcoholic solution of potassium or sodium hydroxide, the reaction being represented thus:

But it is clear that we might expect the results in some cases to be represented thus:

and, in other cases, the product might contain both dipotassium salt and the potassium alkyl salt.

Experiments were made with the esters of a number of dibasic acids. The ester was dissolved in the corresponding alcohol and the solution of potassium hydroxide in the same alcohol added in the proportion of a little less than one formula weight of potassium hydroxide to one formula weight of the ester. The precipitate, which usually began to appear after a few cubic centimeters of the alkali solution had been added, was filtered off, washed with the alcohol used and dried at  $100^{\circ}$ . This precipitate was analyzed by boiling with an excess of standard potassium hydroxide solution for about one and one-half hours, using a reflux condenser, and titrated back with standard acid, using phenolphthalein as indicator.

Oxalic esters gave practically pure potassium alkyl oxalate.

Tartaric esters gave potassium alkyl tartrate and a little dipotassium tartrate.

Succinic esters gave potassium alkyl succinate and considerable dipotassium succinate.

Phthalic esters gave dipotassium phthalate only.

Experiments with sodium hydroxide gave, in some cases, precipitates which would not crystallize and the reaction of oxalic esters with potassium hydroxide was selected for further study. It was found that for obtaining pure potassium alkyl oxalate from a dialkyl oxalate it is better not to use a very dilute solution of the ester, not to raise the temperature of the solution, and to use noticeably less than the calculated amount of potassium hydroxide.

Saloman<sup>1</sup> noticed that if ethyl oxalate be treated with a solution of potassium methylate in methyl alcohol the product was potassium methyl oxalate and he suggested representing this reaction in two stages:

Saloman's experiment was repeated, using an alcoholic solution of potassium hydroxide. Ten grams of diethyl oxalate were dissolved in 50 cc. methyl alcohol and 89 cc. of 0.767 *N* potassium hydroxide solution (in methyl alcohol) added, drop by drop, with constant shaking, the temperature being kept about  $0^{\circ}$ . This was the only case where it was found necessary to work below room temperature. The precipitate was washed with 50 cc. methyl alcohol, dried, and titrated as shown above. The re-

<sup>1</sup> *Ber.*, 8, 1509 (1875).

sult of the titration showed the precipitate to be potassium methyl oxalate. Solutions of potassium hydroxide in other alcohols were used with diethyl oxalate and also with other oxalic esters and the results are given in Table I.

TABLE I.—EFFECT OF KOH ON OXALIC ESTERS.

Diethyl oxalate.		Dimethyl oxalate.		Diisooamyl oxalate.	
Solvent alcohol.	Result.	Solvent alcohol.	Result.	Solvent alcohol.	Result.
Methyl	K methyl oxalate	Ethyl	K ethyl oxalate	Methyl	K methyl oxalate
Propyl	K propyl oxalate	Propyl	K propyl oxalate	Ethyl	K ethyl oxalate
Isoamyl	K isoamyl oxalate	Isobutyl	K isobutyl oxalate	Propyl	K propyl oxalate
		Isoamyl	K isoamyl oxalate	Isobutyl	K isobutyl oxalate

In every case the oxalic ester when treated with slightly less than the calculated amount of potassium hydroxide in alcoholic solution gave a practically pure potassium alkyl salt in which the alkyl corresponded to the alcohol used as solvent. Further experiments showed that if mixed alcohols were used as solvent the product consisted of the two potassium alkyl salts corresponding to the alcohols used.

(a) Dimethyl oxalate with potassium hydroxide in a solvent consisting of ethyl alcohol and acetone in equal proportions gave potassium ethyl oxalate.

(b) Dimethyl oxalate was dissolved in ethyl alcohol and, after two hours, the alcohol was evaporated and the remaining ester was pure, unchanged dimethyl oxalate.

Some solubility determinations were made at room temperature with the following results:

100 cc. methyl alcohol dissolved:  
 3.0 g. potassium methyl oxalate  
 5.6 g. potassium ethyl oxalate  
 0.016 g. dipotassium oxalate

100 cc. ethyl alcohol dissolved:  
 0.15 g. potassium methyl oxalate  
 0.30 g. potassium ethyl oxalate  
 0.004 g. dipotassium oxalate

The precipitation of potassium alkyl oxalate rather than dipotassium oxalate is not due to greater insolubility of the former and, also, the precipitation of potassium ethyl oxalate rather than potassium methyl oxalate from ethyl alcohol solution is not due to greater insolubility of the potassium ethyl oxalate.

It would be possible to represent the reaction we are considering in three ways:

If either (2) or (3) is the better representation we might expect to find dimethyl oxalate or methyl ethyl oxalate in the residual dialkyl ester when considerably less than the calculated amount of potassium hydroxide solution is used.

Four cc. diethyl oxalate were dissolved in 10 cc. methyl alcohol and to this was added 2 cc. of 0.769 *N* potassium hydroxide solution in methyl alcohol but no precipitate was obtained although it was left for several hours. The alcohol was allowed to evaporate at room temperature and the dialkyl ester extracted with chloroform. The oily residue obtained by evaporation of the chloroform at room temperature might be diethyl oxalate, diethyl oxalate and dimethyl oxalate or diethyl oxalate and methyl ethyl oxalate but could not be dimethyl oxalate since the melting point of the latter is 54°. This residue was titrated and the results indicate either 7.5% dimethyl oxalate and 92.5% diethyl oxalate or 16.8% methyl ethyl oxalate and 83.2% diethyl oxalate.

Table II contains the data of a series of experiments in which varying amounts of 0.769 *N* solution of potassium hydroxide in methyl alcohol were used with 4 cc. ethyl oxalate dissolved in 10 cc. methyl alcohol. The 4 cc. ethyl oxalate used would require 38.5 cc. of the potassium hydroxide solution to completely convert it to potassium alkyl oxalate and the amount of this solution used is expressed in the first row of the table as the percentage of the total amount necessary to convert the diethyl oxalate to potassium alkyl salt. As the last three experiments in the series gave residual esters containing crystals of dimethyl oxalate the analyses of these residual esters were interpreted as indicating the proportions of dimethyl oxalate and diethyl oxalate and these appear in the last row. The analyses were done in duplicate and the average taken.

TABLE II.

Diethyl Oxalate (4 cc.) Dissolved in 10 cc. of Methyl Alcohol.

KOH sol. Me alc., %.....	5.2	10.4	15.6	20.8	26.0
Dimethyl oxalate, %.....	7.5	33.0	59.5	84.6	98.7

The results of this series of experiments show that a methyl alcohol solution of potassium hydroxide converts diethyl oxalate into dimethyl oxalate and that the amount of dimethyl oxalate formed depends on the amount of potassium hydroxide used. This reaction is accompanied by another reaction which produces potassium methyl oxalate. If, in the last experiment, a further amount of 28.5 cc. of the potassium hydroxide solution had been added there would have been complete conversion to potassium methyl oxalate and it would have been the conversion of dimethyl oxalate and not of diethyl oxalate to potassium methyl oxalate.

The two stages of the reaction are, therefore, represented as first, the change of diethyl oxalate to dimethyl oxalate and, second, the change of dimethyl oxalate to potassium methyl oxalate, see (2) above.

Since experiment (b) on page 1805 showed that an oxalic ester is not converted to a different ester by treatment with another alcohol, the change must take place under the influence of the alcoholic solution of potassium hydroxide or, possibly, the potassium alkyl salt first formed acts as a catalyzer for the reaction.

Potassium ethyl oxalate was added to ethyl oxalate dissolved in methyl alcohol and, after a few hours, the dialkyl ester was found to be unchanged diethyl oxalate.

In a solution of potassium hydroxide in methyl alcohol it may be considered that potassium hydroxide and potassium methylate are in equilibrium. Addition of water to this solution would disturb this equilibrium forming more potassium hydroxide. Hence, the addition of water to the potassium hydroxide solution would hasten or retard the formation of dimethyl oxalate depending on whether the potassium hydroxide or the potassium methylate is the determining influence in the reaction.

Table III contains the results of experiments in which the solutions of potassium hydroxide in methyl alcohol contain varying amounts of water. These solutions were made up by adding the necessary weight of water to the methyl alcohol solution of the potassium hydroxide and the methyl alcohol used for dissolving the diethyl oxalate was also diluted with water.

TABLE III.

26.0	17.9	31.2	16.9	46.8	17.0	78.0	20.0	26.0	39.9
31.2	23.5	36.4	22.6	57.2	28.0	..	..	..	..
..	..	..	..	67.6	38.5	..	..	..	..

Table III shows that under the influence of a given amount of potassium hydroxide dissolved in methyl alcohol much less dimethyl oxalate is formed when water is present and that the more water is present the less dimethyl oxalate is formed. It must be considered that the potassium methylate rather than the potassium hydroxide is the influence causing the reaction.

The last two columns which record experiments in which the alcohol was diluted with acetone instead of water shows a smaller production of dimethyl oxalate than when pure methyl alcohol was used but a much greater production than when the alcohol was diluted with the corresponding amount of water.

The results of these experiments have been represented graphically, using as one axis the amount of potassium hydroxide solution used (expressed as the percentage of the amount necessary to completely convert the diethyl oxalate to potassium methyl oxalate) and, as the other axis the percentage of dimethyl oxalate found in the residual dialkyl ester.

Saloman's representation of this reaction need not be seriously considered. It would be better to assume the formation of an addition compound of the ester with the potassium alcoholate, but, with the information at present available, it is not thought that this would help in the study of the reaction.

### Summary.

1. Dialkyl oxalates, when treated with slightly less than the calculated amount of potassium hydroxide in alcoholic solution, give a practically pure potassium alkyl oxalate in which the alkyl corresponds to the alcohol used as solvent.
2. A few solubility determinations were made which indicate that the results obtained in these experiments do not depend on the relative insolubility of the possible potassium alkyl salts.
3. If much less than the calculated amount of the methyl alcohol solution of potassium hydroxide is used with diethyl oxalate the residual dialkyl ester contains an amount of dimethyl oxalate which depends on the amount of potassium hydroxide solution used.

4. The change from diethyl oxalate to potassium methyl oxalate is represented as, first, the change of diethyl oxalate to dimethyl oxalate and, second, the change of dimethyl oxalate to potassium methyl oxalate.

5. The presence of potassium ethyl oxalate in the solution of diethyl oxalate in methyl alcohol does not cause the formation of any dimethyl oxalate.

6. If the solution of potassium hydroxide in methyl alcohol be said to contain potassium hydroxide and potassium methylate, the potassium methylate is a stronger factor than the potassium hydroxide in causing the change from diethyl oxalate to dimethyl oxalate.

These experiments were done under the direction of Professor F. B. Allan and it is proposed to continue them using solutions of other alkalies.

TORONTO, CANADA.

## HALOGENATION. XI. CHLORINATION WITH AQUA REGIA. THE CHLORINATION OF HYDROCARBONS.

BY RASIK LAL DATTA AND FRANCIS VITO FERNANDES.

Received June 17, 1916.

In continuation of the study of the chlorination of hydrocarbons by means of aqua regia,<sup>1</sup> several other hydrocarbons were subjected to its action. The results obtained were, however, mostly unsatisfactory, except in the case of a few hydrocarbons whose chloro-derivatives could be isolated by distillation or crystallization. Aqua regia has a nitrating influence on account of the nitric acid, as well as a chlorinating influence on account of the nascent chlorine. The lower hydrocarbons give only chloro-derivatives while the higher homologs usually give a mixture of both chloro- and nitro-derivatives. The reagent is quite unsuitable for chlorinating the higher hydrocarbons, while it can be successfully applied for the chlorination of the lower ones. The chlorination of the xylenes, ethyl benzene and dibenzyl gives good results; the rest of the hydrocarbons treated, either give a complicated product which cannot be separated, or break up with the formation of chloropicrin, which, as will be shown later on, is the general decomposition product under these circumstances.

### Experimental.

***m*-Xylene.**—In a typical experiment, 30 cc. of *m*-xylene were chlorinated for about six hours with 360 cc. of the mixture of HCl and HNO<sub>3</sub> (2 : 1). The mixture was heated in a flask on the wire gauze with a reflux condenser. The product was well washed with water and alkali, and kept overnight over calcium chloride.

The liquid, 25 cc., was decanted, and distilled with a stillhead. The dis-

<sup>1</sup> Datta and Fernandes, *THIS JOURNAL*, 36, 1007 (1914).

tillate was collected in two fractions, *viz.*, (1) from 140–190°, (2) from 190–224°. The volumes of the two fractions were 15.5 cc. and 9.5 cc., respectively. Thus it seemed that monochloroxylylene was formed in predominant quality, while the 4,6-dichloroxylylene was formed in slightly smaller proportion.

The two fractions were subjected to fractional distillation. After carrying out the process repeatedly, about 9 cc. of pure monochloroxylylene were obtained from the first fraction. The second fraction similarly yielded 5 cc. of pure 4,6-dichloroxylylene. These were identified in the usual manner.

The residue that was left in the distilling flask crystallized on cooling. Thin, white needles were obtained, which were pressed between the folds of filter paper and then dried in the desiccator. The melting point of the crystals was not sharp at all: it extended over a range of 15° from 195 to 210°. Thus it appeared that a mixture of chloro-derivatives was formed. Hence the solid was fractionally crystallized from hot alcohol. After the first crystallization the substance deposited from the alcoholic solution gave the m. p. 208°, although not sharp. A second crystallization gave the pure 2,4,5,6-tetrachloroxylylene with the m. p. 210°.

0.1037 gave 0.2432 AgCl; Cl = .58.01; Calc. for  $C_6Cl_4(CH_3)_2$ : Cl = 58.19.

The main portion of the substance insoluble in alcohol gave, on repeated crystallization, a small amount of trichloroxylylene, m. p. 117°. Hence the solid from the residue of distillation consisted mainly of the 2,4,5,6-tetrachloroxylylene contaminated with trichloroxylylene.

In a second experiment 25 cc. of *m*-xylene were subjected to prolonged chlorination under the conditions described above. The action was allowed to proceed for 35 hours and the mixture of acids was renewed every 5 hours, 180 cc. being used each time. After about 10 hours crystals were seen all over the liquid. The product was treated as before and kept in the vacuum desiccator. After 24 hours, it was found that crystals were deposited from the liquid. They were filtered out and drained well with suction. The liquid chloro-derivatives on distillation behaved as in the first experiment and consisted of mono- and dichloro-xylenes. The residue in the distilling flask solidified. The solid melted at about 188°. The crystals which were deposited from the liquid in vacuum also melted at about 190°. By fractional crystallization both products could be separated into the tri- and tetrachloroxylenes. The total solid product weighed 1.3 g. and on fractional crystallization gave 1.1 g. of 2,4,5,6-tetrachloroxylylene. Hence the method is specially applicable for the preparation of the tetrachloro-derivative of *m*-xylene.

***o*-Xylene.**—20 cc. of *o*-xylene were mixed with 360 cc. of the mixture of acids, and the whole heated on the wire gauze with a reflux condenser,

for about 8 hours. The product, after being separated and washed was dried in the desiccator.

The liquid deposited crystals, m. p.  $210^{\circ}$ .

The filtrate (16.5 cc.) was distilled with a stillhead and the distillate collected as follows: (1) from  $142$  to  $200^{\circ}$ , and (2) from  $200$  to  $230^{\circ}$ . The amounts of the two fractions were 11 cc. and 3.5 cc., respectively. These fractions were then distilled fractionally till they yielded products which had constant boiling points. The first gave 8.5 cc. of monochloroxylylene with the boiling point  $191.5^{\circ}$ , and the second about 1.2 cc. of 4,5-dichloroxylylene which boils at  $227^{\circ}$ .

The residue in the distilling flask solidified and the solid had the m. p.  $208^{\circ}$ . The two solids obtained must have been identical. They were crystallized from acetone, and in each case a pure solid was obtained which had the m. p.  $215^{\circ}$  and could be sublimed.

0.0917 gave 0.2177 AgCl; Cl = 58.73%. Calc. for  $C_6Cl_4(CH_3)_2$ : Cl = 58.19.

Hence the product was 3,4,5,6-tetrachloroxylylene.

***p*-Xylene.**—25 cc. of *p*-xylene were mixed with 180 cc. of the mixture of acids and heated on the wire gauze in a flask with a reflux condenser. The operation was conducted for about ten hours, the acids being renewed after five hours. The product was separated, washed and dried over calcium chloride.

In distilling the product, the maximum temperature attained was  $230^{\circ}$ . The following fractions were collected: (1)  $170$ – $200^{\circ}$ , (2)  $201$ – $230^{\circ}$ . The fractions were purified by fractional distillation; the first gave the b. p.  $186.8^{\circ}$ , and the second  $222^{\circ}$ . Thus the chloro-derivatives formed were chloroxylylene,  $C_6H_3Cl(CH_3)_2$ , and 2,5-dichloroxylylene,  $C_6H_2Cl_2(CH_3)_2$ . The quantities obtained were as follows: Volume of the whole product, 22.5 cc.; volume of chloroxylylene, 4.3 cc.; volume of 2,5-dichloroxylylene, 5 cc.

The residue in the distilling flask solidified on cooling. The solid was fractionally crystallized from hot alcohol. The pure crystals melted at  $217.5^{\circ}$ , and were soluble in ether and benzene.

0.1258 gave 0.2976 AgCl; Cl = 58.53. Calc. for  $C_6Cl_4(CH_3)_2$ : Cl = 58.19.

Thus the solid was tetrachloroxylylene. Its weight was about 0.8 g.

Hence the method is suitable for the preparation of all the derivatives mentioned above, as they are produced in fair quantities in a single operation.

In another experiment 25 cc. of *p*-xylene were treated as above for double the length of time, in order to see whether the amount of the end product had increased. There was a slight increase, but the chloroxylylene was also formed in an appreciable quantity.

**Ethyl Benzene.**—25 cc. of ethyl benzene were mixed with 360 cc. of the mixture of acids and heated on the wire gauze for about six hours.

The product was treated as usual and distilled. The temperature rose to  $206^{\circ}$ . The fraction collected between  $180$  and  $206^{\circ}$  was subjected to fractional distillation. The pure sample gave the b. p.  $201^{\circ}$ .

0.0917 gave 0.0925 AgCl; Cl = 24.95. Calc. for  $C_8H_9Cl$ : Cl = 25.26.

Hence monochloroethylbenzene,  $C_6H_5CH_2CH_2Cl$ , was formed. The quantity of this chloro-derivative was about 6 cc.

As indicated in the above investigation, the chlorine is introduced in the side-chain. To ascertain whether it was at all possible to replace the hydrogen in the nucleus, the following elaborate chlorination process was carried out: 25 cc. of the hydrocarbon were chlorinated for 37 hours, the reagent being renewed every four hours. After about 8 hours the liquid became heavy and sank beneath the acids, thus showing that the product had greater density. When the liquid was cooled a fine crop of silky white crystals was noticed, which dissolved on shaking. The crystals were formed in larger quantities at the end of the experiment.

The product was very thick in consistency. It was washed with water and alkali by decantation, the water being removed as much as possible by means of blotting paper. It was finally dried over sulfuric acid in a vacuum desiccator.

The liquid was found to have deposited crystals which had the m. p.  $160$ – $170^{\circ}$ . The little remaining liquid was subjected to distillation. The temperature rose to  $210^{\circ}$ . Thus the monochloro-derivative was formed in small quantity.

The crystals were fractionally crystallized from acetone until pure. The final product had the m. p.  $171.5^{\circ}$ . As no known chloro-derivative of ethylbenzene has this m. p. the sample is being completely investigated.

**Dibenzyl.**—The substance was treated with the mixture of acids for about four hours, the heating being done on the water bath. A brown, oily liquid was obtained, which was separated, washed with water and alkali, and dried in the vacuum desiccator. Crystals were deposited, which had the m. p.  $111^{\circ}$ . Analysis indicated the product to be pure *p*-dichlorodibenzyl,  $C_6H_4ClCH_2CH_2C_6H_4Cl$ .

0.0719 gave 0.0830 AgCl; Cl = 28.57. Calc. for  $C_6H_4ClCH_2CH_2C_6H_4Cl$ : Cl = 28.28.

**1,3,5-Butyl Xylene.**—By the chlorination of 1,3,5-butyl xylene a yellow oil was obtained from which no pure chloro-derivatives could be isolated. The smell of chloropicrin was noticed, which is a product of the action of aqua regia on several organic bodies.

Anthracene is chlorinated, to a certain extent, but the greater part of it is oxidized to anthraquinone by the nitric acid. With phenanthrene a sticky mass is obtained which does not contain any nitrogen and which is a mixture of monochlorophenanthrene and phenanthrene which could not be separated. Triphenylmethane gives a mixture of chloro-derivatives

which could not be separated. Diphenylmethane and fluorene give a mixture of chloro-derivatives, respectively, which could not be separated and isolated and in these cases no nitration takes place. In the case of naphthalene it has been found that no chlorination at all takes place, but the naphthalene is nitrated. Cymene, styrene and tetrahydronaphthalene are nitrated and chlorinated. Hydrocarbons which undergo decomposition under the influence of aqua regia, such as cymene, styrene, amylene, diisobutylene, triisobutylene, give chloropicrin which is generally a product of such decompositions, as will be shown later on. Cyclohexane, on account of its volatile nature, could not be chlorinated by means of aqua regia, whereas dimethylcyclohexane is simultaneously nitrated and chlorinated.

## HALOGENATION. XII. THE FORMATION OF CHLOROPICRIN AND TETRACHLOROQUINONE BY THE ACTION OF AQUA REGIA ON ORGANIC SUBSTANCES.

By RASIK LAL DATTA AND NIHAR RANJAN CHATTERJEE.

Received June 17, 1916.

In a previous communication<sup>1</sup> it has been shown that chloropicrin is formed by the action of aqua regia on several organic substances. It has now been found that whenever an organic compound breaks up destructively under the influence of aqua regia, chloropicrin is invariably produced. The chloropicrin formed is sometimes accompanied by very small quantities of other chloronitroderivatives of methane. In the case of certain aromatic compounds, tetrachloroquinone is formed as the end product of the action of aqua regia on them. As tetrachloroquinone itself breaks up to chloropicrin under the influence of aqua regia, the latter is also formed under such decompositions. The formation of chloropicrin has been noticed only in isolated cases by previous workers.

Stenhouse<sup>2</sup> showed that chloropicrin is formed by the distillation of nitro compounds with bleaching powder solution. Kekulé<sup>3</sup> obtained it by the distillation of alcohol with sodium chloride, potassium nitrate and sulfuric acid. Later on, he again prepared the substance by the action of strong nitric acid on chloral.<sup>4</sup> The action of the same reagent on chloroform was found to give chloropicrin.<sup>5</sup> Levy and Jedicka<sup>6</sup>

<sup>1</sup> Datta and Chatterjee, *THIS JOURNAL*, **37**, 567 (1915).

<sup>2</sup> *Ann.*, **66**, 241 (1848).

<sup>3</sup> *Ibid.*, **101**, 212 (1857).

<sup>4</sup> *Ibid.*, **106**, 144 (1858).

<sup>5</sup> Mills, *Ibid.*, **160**, 117 (1871).

<sup>6</sup> *Ann.*, **249**, 86 (1888).

showed that this can be obtained by the action of chlorine on nitranilic acid. Hofman<sup>1</sup> gave a method for the preparation of this compound by the action of bleaching powder on picric acid.

On examining the above modes of formation, it will be noticed that they fall into two classes. The first is the distillation of nitro compounds with bleaching powder and the second is the action of nitric acid on halogenated organic compounds containing at least three chlorine atoms. The first mode requires that the decomposing substance must have a nitro group, while the second requires the presence of three chlorine atoms, these representing the two kinds of groups attached to the carbon atoms in chloropicrin. But it was thought possible, that such a condition might be obviated altogether by subjecting any organic compound liable to such decomposition, to the simultaneous action of both nascent chlorine and nitro group; and this has been found possible. Such a reagent has been found to be aqua regia. From a study of a large number of cases, it has been found that when aqua regia acts upon a substance—no matter if it does not contain any chlorine or nitro group—chloropicrin is invariably produced, provided the substance has a tendency to decompose destructively. The formation of chloropicrin fails under those cases in which the substance is quite stable in the presence of aqua regia and has no tendency to decompose. In those cases in which chloropicrin is formed, the yield of chloropicrin obtained varies. In some cases a quantitative yield of chloropicrin is obtained, in others it is produced in moderate quantity and again in some a trace of it is formed.

Again, the formation of chloranil has been studied in a very limited number of cases. Chloranil is formed by leading chlorine into an alcoholic solution of chlorisatin.<sup>2</sup> It has been obtained by the action of a mixture of hydrochloric acid and potassium chlorate on aniline, phenol,<sup>3</sup> salicylic acid, nitrosalicylic acid and dinitrosalicylic acid.<sup>4</sup> It has also been obtained by the action of the same reagents on tyrosin<sup>5</sup> and on *m*-amino-benzoic acid.<sup>6</sup> By the interaction of fuming nitric acid on perchlorophenol, Merz and Weith<sup>7</sup> obtained chloranil. Beilstein and Kurbatow<sup>8</sup> obtained it from 1,2,4,5-tetrachlorobenzene. Barral<sup>9</sup> obtained chloranil from hexachlorocyclohexadion by means of fuming nitric acid. Elbs and Brunnschweiler<sup>10</sup> gave a method of its preparation from aniline, sodium

dichromate and hydrochloric acid. Witt and Toechemittler<sup>1</sup> prepared chloranil by the treatment of 2 : 6-dichloro-*p*-phenylenediamine with potassium chlorate and hydrochloric acid. Chloranil is prepared by Graebe,<sup>2</sup> from *p*-phenylenediamine with potassium chlorate and hydrochloric acid and oxidizing the product by means of acid dichromate. It is manufactured on the large scale by the treatment of 2,4,6-trichlorophenol with chromic acid mixture. Bouveault<sup>3</sup> treats commercial chloranil with fuming nitric acid and potassium chlorate with the view of oxidizing the lower chloroquinones. One of us<sup>4</sup> has described reactions for the preparation of chloranil from *p*-phenylenediamine and hydroquinone by the action of aqua regia, which has been shown to be a good method for the preparation of chloranil.

It is evident from the above that chloranil has been prepared from a large number of sources and no generalization of their formation has as yet been noticed. It will be shown, from the study of a large number of cases, that the formation of chloroquinones is quite general in certain classes of compounds. By the action of aqua regia, which has a far greater oxidizing and chlorinating action than potassium chlorate and hydrochloric acid, on aromatic compounds, chloranil is very frequently formed; and as chloranil itself breaks up into chloropicrin by the action of aqua regia, this is also a general product of such reactions.

The essential condition of the formation of chloranil is that the aromatic compounds which are substituted in the *p*-positions, by particularly easily replaceable groups, yield tetrachloroquinone readily and with good yield, since the influence of side reaction is quite small in those cases. In the case of hydroxy and amino substituted products, chloranil is formed, but is accompanied by a large amount of tarry and other secondary products. In such cases the substance passes through a quinoid structure during the treatment with aqua regia. Again in those compounds which already possess simple or complex quinoid structures, chloranil is formed tolerably readily and in good yield. For instance, hydroquinone, which readily gives quinone on oxidation, yields tetrachloroquinone in almost quantitative yield by the action of aqua regia. Aniline black, which possesses a complex quinoid structure, yields chloranil easily. In the case of compounds which contain complex nuclei, such as naphthalene and anthracene derivatives, the formation of chloranil does not take place, the only effect is the formation of varying quantities of chloropicrin with considerable charring of the products. In the case of compounds which are otherwise substituted, considerable charring is the result with the formation of chloropicrin.

<sup>2</sup> *Ann.*, 263, 16 (1891).

<sup>3</sup> *Ann. chim. phys.*, [8] 13, 142 (1908).

<sup>4</sup> Datta, *THIS JOURNAL*, 36, 1011 (1914).

In a preliminary communication<sup>1</sup> the action of aqua regia on acetone, ether, ethyl, methyl and allyl alcohols, acetic and formic acids have been studied and it has been shown that an almost quantitative yield of chloropicrin is formed in the case of acetone suitable for the preparation of this substance in the laboratory. The action of aqua regia on the following substances has been further studied:

### Aliphatic Compounds.

*Propyl Alcohol.*—5 cc. of propyl alcohol are added to 25 cc. of a mixture of nitric and hydrochloric acids (1:2) and the whole is warmed on the water bath for three to four hours. At the end of the operation, a very pungent odor of chloropicrin is noticed and at the same time a small quantity of an oil separated. The whole is subjected to steam distillation, when a colorless oil distils over and collects at the bottom of the aqueous layer. This is pure chloropicrin as is identified by its boiling point which is between 112 to 113°.

0.2537 gave 0.6471 AgCl; Calc. for  $\text{CCl}_3\text{NO}_2$ : Cl = 64.02. Found: Cl = 63.10.

*Isopropyl Alcohol.*—The decomposition of isopropyl alcohol to chloropicrin is almost quantitative, since its immediate oxidation product is acetone, which has been found to give a good yield of chloropicrin. 10 cc. of isopropyl alcohol are added to 50 cc. of aqua regia, when an instantaneous vigorous reaction takes place with the separation of a large quantity of an oil. The reaction is completed by heating on the water bath. The product is distilled with steam and the oil collected, which, when dried and distilled, is found to be chloropicrin boiling at 112–113°.

0.1524 gave 0.3890 AgCl; Calc. for  $\text{CCl}_3\text{NO}_2$ : Cl = 64.02. Found: 63.24.

*Butyl Alcohol.*—10 cc. of butyl alcohol are taken in a flask and to this about 50 cc. of a mixture of nitric and hydrochloric acids (1:2) are added and the whole is warmed on the water bath with a reflux for three hours. A colorless oil begins to collect at the bottom which increases in quantity as the operation goes on. The whole was subjected to steam distillation and identified as usual to be chloropicrin boiling between 112–113°.

*Isobutyl Alcohol.*—5 cc. of isobutyl alcohol are added to 25 cc. of aqua regia. Only a slight reaction takes place in the cold, increasing somewhat on warming. After the end of the reaction no oil separates but a pungent smell of chloropicrin is produced, indicating that this compound is decomposed only partially.

*Glycerol.*—10 cc. of glycerol are taken in a flask fitted with a reflux condenser and to it 60 cc. of aqua regia are added. There is no reaction in the cold, but on warming on water bath a reaction seems to take place. The operation is continued for four hours. After the operation no oil separates, but a pungent smell of chloropicrin is noticed, which points to the fact that the chloropicrin which is formed only in small quantities is kept dissolved in dilute acids. The chloropicrin is secured by steam distillation and identified as usual.

*Cane sugar* gives a very small yield of chloropicrin on account of the fact that it is oxidized rapidly by the nitric acid to stable compounds such as oxalic acid. To 5 g. of cane sugar in a flask, 50 cc. of aqua regia are added. No reaction takes place in the cold, but on warming on the sand-bath reaction goes on with the charring of the sugar. On continuing the operation for three to four hours, the solution which smells distinctly of chloropicrin ultimately turns yellow.

*Maltose* gives only a trace of chloropicrin when 5 g. of maltose are heated on a reflux apparatus with 60 cc. of aqua regia. After the mixture is heated on the sand bath for

<sup>1</sup> *Loc. cit.*

four to five hours a pale yellow solution is left which has only a faint smell of chloropicrin.

*Grape sugar* is warmed on the sand bath when a trace of chloropicrin is formed.

*Starch* is warmed on the sand bath with aqua regia for three hours. At the end of the operation only a slight smell of chloropicrin is noticed.

*Methyl Ethyl Ketone*.—On treating methyl ethyl ketone with aqua regia on the water bath, a complete decomposition of the ketone takes place and an almost quantitative yield of chloropicrin is the result, which is identified as usual.

*Diethyl ketone* decomposes on treatment with aqua regia and a good yield of chloropicrin is obtained.

*Tartaric acid* is heated on the sand bath with aqua regia for several hours. In this case, no smell of chloropicrin could be noticed. Hence the substance is quite stable in the presence of aqua regia and does not decompose destructively.

*Chloroform*.—10 cc. of chloroform are treated with 60 cc. of aqua regia. No action takes place in the cold, but it goes on slowly as it is heated on the water bath with reflux. At the end of the operation only a slight smell of chloropicrin could be noticed.

*Chloral Hydrate*.—When 5 g. of chloral hydrate are treated with 30 cc. of aqua regia the reaction starts in the cold. The mixture is warmed on the water bath under reflux for three hours. At the end of the operation, a strong smell of chloropicrin is noticed.

*Allyl Mustard Oil*.—To 25 cc. of aqua regia, 4 cc. of allyl mustard oil are slowly added. At first no reaction takes place, but after a time a vigorous reaction ensues with the frothing up of the mixture. When the reaction has subsided, the whole is heated on the sand bath for two hours. At the end of the operation a pale yellow oil is found under the acid mixture. This is distilled in steam and the chloropicrin obtained is identified as usual.

*Carbamide* is heated under reflux with aqua regia for a good length of time. At the end only a slight smell of chloropicrin is noticed, pointing to the fact that urea is decomposed to a slight degree under the influence of aqua regia to form chloropicrin.

*Guanidine carbonate* is heated under a reflux on a sand bath with aqua regia. Only a trace of chloropicrin is formed which is recognized by its odor. It appears that the formation of stable salts hinders the decomposition of the compound to chloropicrin.

*Hexamethylenetetramine* is heated with an excess of aqua regia on the water bath for several hours. At the end of the operation, a colorless solution is obtained which smells only slightly of chloropicrin.

*Uric acid* is treated with aqua regia. At first no reaction takes place but after five minutes, bubbles of gas begin to rise, the substance going into solution gradually until it is completely dissolved. The mixture is heated on the sand bath for three to four hours. The resulting solution had a distinct smell of chloropicrin.

*Theobromine* on heating with the acid mixture yields a solution which smells slightly of chloropicrin.

*Caffeine*.—When the acid mixture is added to caffeine, a reaction takes place at once. The mixture is warmed on the sand bath for three to four hours. At the end the resulting solution smells distinctly of chloropicrin but no oil separates at the bottom. Hence the amount of chloropicrin formed is only minute.

### Aromatic Compounds.

*p-Aminophenol*.—On adding *p*-aminophenol to a mixture of nitric and hydrochloric acids, at first there is no action, but soon afterwards the action commences with frothing. The mixture is then warmed on the water bath for two hours, and at the end of the operation a sulfur yellow crystalline product is produced. In this case no tarry

product is formed. The yellow product obtained is crude chloranil which is purified by sublimation and is found to melt at  $289^{\circ}$  in a sealed capillary tube.

0.1621 gave 0.3728 AgCl; Calc. for  $C_6Cl_4O_2$ : Cl = 57.14. Found: 56.89.

The supernatant liquid smells strongly of chloropicrin. Hence chloropicrin is formed at the same time, which is isolated and identified in the usual manner.

*2,4-Diaminophenol*.—This was heated under a reflux with aqua regia for three hours. The product consists of a yellowish liquid smelling strongly of chloropicrin and at the same time, a yellowish brown semisolid product is deposited underneath. It was filtered, washed and dried. On sublimation, the mass charred and a sublimate was obtained in beautiful yellow plates, melting at  $289^{\circ}$ , which is pure chloranil. In this case the yield is very small, as a considerable portion is converted to a tarry mass with the formation of a large amount of chloropicrin.

*p-Diaminodiphenylamine*.—On treating the substance with aqua regia, at first very slight reaction takes place, which however is found to go on slowly on heating under reflux on a water bath. At the end of three hours, a brown solid substance is seen floating at the time, while the mixture smells strongly of chloropicrin. The operation is continued with a fresh quantity of aqua regia for some time. The brown product on sublimation gave a small yield of chloranil. 10 g. of the substance yielded 3 g. of tetrachloroquinone.

*Sulfanilic acid* is treated with aqua regia when it begins to dissolve slowly. The mixture is then warmed on the water bath under reflux when within an hour, a yellowish crystalline product is seen to be formed on the surface of the acid mixture, which gradually increases in quantity during the progress of the reaction. After three hours the operation is found to be complete, and the product obtained consists of beautiful yellow crystalline scales which is nearly pure chloranil. It is purified by a single sublimation. The supernatant liquid smells strongly of chloropicrin, pointing to the fact that a good quantity of sulfanilic acid is decomposed to chloropicrin.

*p-Nitrophenol*.—On heating *p*-nitrophenol with aqua regia for several hours, a sulfur yellow crystalline solid is obtained without any charring of product. The solution smells strongly of chloropicrin. On sublimation pure tetrachloroquinone is obtained melting at  $289^{\circ}$ .

*p-Hydroxybenzoic Acid*.—On heating *p*-hydroxybenzoic acid with aqua regia for several hours, a good yield of chloranil is obtained. This is unaccompanied by any tarry matter. The solution smells strongly of chloropicrin.

*p-Toluidine*.—When this is treated with aqua regia a reaction takes place at once. The mixture is warmed on the water bath when a dark oily substance is formed which deposits at the bottom. The liquid also smells strongly of chloropicrin. Upon prolonging the operation beautiful crystals are formed which are not chloroquinone. The product is under examination.

*p-Cresol* yields on prolonged treatment with aqua regia a smell of chloropicrin and a brown product is obtained which, however, does not yield any chloranil.

*Aniline*.—To aqua regia, aniline is added very gradually. At the end of the addition, a dark tarry product is seen floating on the acid mixture. The product is warmed on the water bath for six hours, during which the pungent smell of chloropicrin is noticed. As the operation is in progress the acid mixture is renewed. A brown pasty mass is obtained which yields a small quantity of tetrachloroquinone.

*Diphenylamine*.—To aqua regia, diphenylamine is gradually added when a reaction takes place, the solution turning dark blue. The product is warmed on the water bath with the renewal of the acid mixture, when a yellowish brown substance is obtained which gives a small yield of chloranil on sublimation. The mother liquid smells strongly of chloropicrin which is also formed in considerable quantity.

**2,4-Dichloroaniline.**—On treating dichloroaniline with aqua regia, a reaction takes place in the cold. It is continued on the water bath and at the end a brown crystalline product is obtained which gave a fair yield of chloranil. The yield in this case is much greater than from aniline or diphenylamine. Chloropicrin is also formed at the same time.

**Phenylhydrazine.**—Phenylhydrazine hydrochloride is added to aqua regia and heated on the water bath. A reaction takes place with the evolution of heat, at the end of which, a tarry product is formed. This on sublimation gives a small yield of chloranil. During the operation the solution has a very pungent smell of chloropicrin.

**Trichlorophenol.**—This compound is heated in a reflux with aqua regia on the water bath. In the course of an hour, the transformation into chloranil is perceptible by the change of brown color of the product to bright yellow and generally becomes complete after three hours. A good yield of chloranil is obtained unaccompanied by any tarry matter. The mother liquor smells strongly of chloropicrin, a good quantity of which is formed at the same time.

**Tribromophenol.**—On treating tribromophenol with aqua regia on the water bath it is found that the bromine is replaced by chlorine and ultimately tetrachloroquinone is the result. A good quantity of chloropicrin is also formed at the same time.

**Aniline Black.**—Aniline black on prolonged treatment gradually turns from black to yellow. At the same time a pungent smell of chloropicrin is noticed. The yellow substance on sublimation gives a good yield of tetrachloroquinone.

**Methyl orange** on treatment with aqua regia, yields beautiful yellow crystals unaccompanied by any tarry matter. This is sublimed to get pure chloranil which is formed in good yield. The yellowish brown liquid smells strongly of chloropicrin.

**Azobenzene** gives a brown product, as also an abundant quantity of chloropicrin. In this case only a trace of tetrachloroquinone could be obtained.

**m-Cresol** on similar treatment yields a brown product from which a very small quantity of chloranil could be isolated, but chloropicrin is formed abundantly.

**m-Phenylenediamine** on treatment with aqua regia first yields a deep brown oily liquid which subsequently turns into a yellow crystalline solid. The yellow crystalline substance gives a fair yield of chloranil. The mother liquid strongly smells of chloropicrin.

**m-Nitraniline** yields a brown semi-solid product which gives a small quantity of chloroanil and an abundant quantity of chloropicrin.

**o-Phenylenediamine** on prolonged treatment yields a tarry mass which does not give tetrachloroquinone. In this case, no chloropicrin is formed.

**o-Nitrophenol** on treatment with aqua regia gradually passes from a dark colored pasty mass to a brown substance and thence to a yellow crystalline product in course of three hours. This yields a fair quantity of chloranil. A good quantity of chloropicrin is also formed at the same time.

**o-Cresol.**—Unlike *m*- and *p*-cresols, *o*-cresol is found to give good quantities of chloranil and chloropicrin.

On treating *o*-cresol with aqua regia, a dark oily product is formed which is converted into a brown crystalline substance as the action is prolonged. This on sublimation gives chloranil. The mother liquor smells strongly of chloropicrin.

**Benzidine.**—With aqua regia, it yields a brown tarry solid which does not give any tetrachloroquinone. But in this case, a good quantity of chloropicrin is formed.

**Benzenesulfonic Acid.**—In this case no chloranil is formed but a good quantity of chloropicrin is formed.

**Benzamide.**—By the action of aqua regia on benzamide, no chloranil is formed but a yellowish white substance is formed which is under examination. In this case no chloropicrin is formed.

*Acetophenone* yields only chloropicrin and no tetrachloroquinone.

*Benzophenone* yields only chloropicrin and no chloranil. An oily substance is formed which seems to decompose to chloropicrin and no sign of the formation of a solid could be noticed.

*Resorcinol*.—By prolonged treatment of resorcinol with aqua regia as usual, a good quantity of chloropicrin is produced and also a black pasty mass, which gradually diminishes in quantity as the reaction is continued being ultimately converted into chloropicrin. In this case no chloranil is formed.

*Pyrogallic acid* yields a good quantity of chloropicrin and a colorless crystalline product which is under investigation.

*Tannic and Gallic Acids*.—The yield of chloropicrin from tannic and gallic acids is considerable. No chloranil is formed in these cases. Compounds which have got many hydroxy groups generally break up destructively with the formation of chloropicrin.

*Saccharine*.—This gives only a slight smell of chloropicrin. It, however, gives no chloranil.

*Pyridine* does not give either chloranil or chloropicrin when treated with aqua regia with which it forms salts.

*Quinoline*, however, is found to give chloropicrin in a slight degree. When heated with aqua regia, showing that the reagent decomposes the quinoline ring only partially.

*Alpha naphthol*.—This substance yields a tarry product from which only a minute quantity of tetrachloroquinone could be obtained. An abundant quantity of chloropicrin is formed.

*Beta naphthol*.—In the case of  $\beta$ -naphthol, a black substance is formed and an abundant quantity of chloropicrin. From the black substance no chloranil could be obtained. The only effect of prolonged action is that the black substance is diminished with the formation of chloropicrin.

Mesitylene, cymene and styrolene all yield chloropicrin with the charring of products. Naphthalene and anthracene yield small quantities of chloropicrin.

### The Preparation of Chloranil.

The preparation of chloranil by the action of aqua regia on hydroquinone and *p*-phenylenediamine has been described in a previous communication and it may be pointed out that they give the best yield of chloranil of any of the substances which have been treated with aqua regia. In fact this would form the best method for the preparation of chloranil on a commercial scale. The existing method of the manufacture of chloranil is the oxidation of trichlorophenol with potassium dichromate. It has been found that the yield could be increased and the product obtained purer by treating trichlorophenol with aqua regia. The next method of importance giving a good yield of chloranil is the treatment of sulfanilic acid with aqua regia. Sulfanilic acid which has amino and sulfonic groups in the *p*-positions is readily converted into chloranil, the sulfonic and amino groups being detached. The yield in this case is not so high as in the previous cases as in a good portion the molecule is ruptured with the formation of chloropicrin. In view of the fact that it is a cheap substance, this would serve as the most economical method of manufacture of chloranil on the large scale. The yields which have been obtained are as follows:

From 20 g. of hydroquinone and also of *p*-phenylenediamine 13 to 14 g. of pure chloranil could be obtained; from 20 g. trichlorophenol, a yield of 10 g. could be realized and from 20 g. of sulfanilic acid, a yield of 6-7 g. could be secured.

## THE REVERSIBLE REPLACEMENT OF ALCOHOLS IN ALDEHYDEALCOHOLATES.<sup>1</sup>

BY MARGUERITE WILLCOX AND ROGER F. BRUNEL.

Received June 21, 1916.

### I. Introduction.

Few systematic attempts have as yet been made to study the variation of the equilibrium in reactions of organic compounds with alteration of the constitution of one of the reacting substances. Such an investigation has been undertaken here with the hope of gaining a more definite knowledge of the relation existing between the structure of aliphatic compounds and their chemical affinity, and of determining what factors play an important part in governing this relationship.

Ostwald<sup>2</sup> believed that the dissociation constants of acids, bases, and salts were determined by the constitution and composition of the substance, and could be considered as a measure of chemical affinity. He investigated the dissociation constants of organic acids at some length; but the relation between the affinity of organic acids, as expressed by their dissociation constants in solution, and their affinity, as exhibited in organic reactions, is by no means clear. In particular such attempts as that of Derick<sup>3</sup> to explain the reactions of all sorts of organic compounds by a consideration of ionization constants cannot be regarded as convincing.

Davis<sup>4</sup> has recently investigated the effect of constitution on chemical affinity by studying the equilibria reached in the hydrolysis of various substituted formamides into amines and formic acid. Since, however, his paper deals primarily with substitution in the benzene ring, the results obtained are not directly comparable with those given in this paper.

The influence which constitution exerts upon the velocity and limit of esterification of several classes of compounds, including saturated and

<sup>1</sup> Dissertation presented by Marguerite Willcox to the Faculty of Bryn Mawr College in partial fulfillment of the requirements for the degree of Doctor of Philosophy.

<sup>2</sup> "Outlines of General Chemistry," p. 373 (1890). This subject has been extensively discussed in the chemical literature. Michael, *J. prakt. Chem.*, N. S., 60, 333, made such data the original basis of his scale of combined influence. Among others who have discussed this subject Wegscheider is particularly to be mentioned *Mon.*, 23, 287; 26, 1265; *Z. Elektrochem.*, 18, 277, and in *THIS JOURNAL*, Derick, 32, 1333 (1910).

unsaturated, aliphatic and aromatic alcohols and acids, was studied by Menshutkin.<sup>1</sup> Table I gives the limit of esterification reached when a limited number of primary and secondary alcohols were esterified with acetic acid and a number of acids with isobutyl alcohol.

TABLE I.

When the tertiary alcohols were esterified with acetic acid, decomposition took place and unsaturated hydrocarbons were formed; consequently the percentage of ester produced was much too low. Only two general conclusions were drawn: first, that the primary, secondary, and tertiary alcohols and acids fell in three separate groups; and second, that an increase in the molecular weight in a homologous series of primary alcohols or acids was accompanied by an increase in the amount esterified. No particular explanation was given for these facts, or for the differences in the amounts of ester formed with isomeric alcohols and acids in the same group. Unfortunately, the differences between the end points reached must, in a number of cases, be less than the experimental error; therefore, there is little opportunity to draw any conclusions regarding the influence of constitution and composition upon the amount of ester formed.

It would appear that any exact knowledge of the relation between chemical affinity, on the one hand, and constitution and composition, on the other, must be based on the investigation of reversible reactions between comparatively simple compounds in which the constitution of but one of the substances is allowed to alter. In this way the effect of changes in constitution on the equilibrium point of the reaction can be clearly traced. With this end in view, the further investigation of a reaction studied by Gadamer<sup>2</sup> and Kuntze,<sup>3</sup> the course of which can be followed

<sup>1</sup> *Ann. chim. phys.*, [5] 20, 289; 23, 14; 30, 81 (1889).

<sup>2</sup> *Arch. pharm.*, 243, 12 (1905).

<sup>3</sup> *Ibid.*, 246, 91 (1908).

polarimetrically, was undertaken. When chloral-*l*-amylalcoholate is treated with any aliphatic alcohol a reaction takes place according to the following equation:

Kuntze carried out two series of experiments with eight inactive alcohols and reached practically the same end point from whichever side of the reaction he started, from which it is evident that a true equilibrium was attained. He measured the rotation of the pure active alcoholate and alcohol in the solvent used and assumed that a linear relation existed between all intermediate values of rotations and percentages of active constituents present. This relationship he made use of in following the velocity and in measuring the end point reached in all the reactions. Proof will be given later that this assumption of a linear relationship was not correct. Since some of his readings were taken two minutes after the constituents were mixed, it seems probable that in preparing the solutions so quickly, accuracy was in some instances sacrificed; consequently no attempt has been made in this work to measure the reaction velocity, an effort being made, rather, to determine the end point of the reaction as accurately as possible. Kuntze<sup>1</sup> has more recently calculated velocity constants for four of these reactions.

## II. Method and Procedure.

In this investigation two series of experiments were carried out, in which chloral-*l*-amylalcoholate and butylchloral-*d*-sec.-butylalcoholate, respectively, were treated with twenty-two inactive alcohols. The reactions are as follows, the optically active radicals being indicated by heavy type:  $\text{CCl}_3.\text{CH}(\text{OH})\text{O}-\text{C}_5\text{H}_{11} + \text{R}-\text{OH} \rightleftharpoons \text{CCl}_3.\text{CH}(\text{OH})\text{O}-\text{R} + \text{C}_5\text{H}_{11}-\text{OH}$ , and

The determinations were carried out in benzene solution at 25°. In every case 0.025 mol of active alcoholate and an equivalent amount of inactive alcohol were accurately weighed into a measuring flask and diluted to 20 cc. The measurements were all taken in a 2-dm. jacketed polarimeter tube, maintained at 25° by a current of water from the thermostat. The polarimeter<sup>2</sup> was a Landolt-Lippich instrument with a half-shade field and with direct vision spectroscope. The source of light was a lime candle heated by an oxy-illuminating gas flame, light corresponding approximately to the sodium D lines being used. The rotations of the solutions could be read to 0.005°. In the series carried out with chloral-*l*-amylalcoholate, duplicates of all but two of the determinations were

<sup>1</sup> Z. *Electrochem.*, 18, 1015 (1912).

<sup>2</sup> No. 58 in the Schmidt and Haensch catalog.

made, which were identical in most cases and never varied by more than  $0.01^\circ$ . In the butylchloral-*d*-sec.butylalcoholate series duplicates of many of the determinations were made, but since the *d*-sec.butyl alcohol is difficult to obtain in large quantities, only one determination was made with part of the alcohols.

The reactions with primary and secondary alcohols were completed within thirty or forty minutes, the rotations having become constant. The tertiary alcohols, however, reacted more slowly, constant rotations

not being obtained in some cases for nearly two hours. When ever duplicates were made one of the solutions was allowed to stand several hours or even overnight, but no further change in the rotation ever occurred.

The determination of the end point in these reactions depends upon the fact that the active alcoholates do not have the same rotations as the active alcohols from which they are formed. It will be noticed that the difference between the rotations of butylchloral-*d*-sec.butylalcoholate and *d*-sec. butyl alcohol is much greater than that between the rotations of chloral-*l*-amylalcoholate and *l*-amyl alcohol; consequently a greater degree of accuracy is afforded by the former series of reactions. For 0.025 mol, 2.2028 g., *l*-amyl alcohol in 20 cc. benzene solution,  $\alpha_D^{25} = -1.13^\circ$ ; for 0.025 mol, 5.8871 g., chloral-*l*-amylalcoholate in 20 cc. benzene

Fig. 1.

solution,  $\alpha_D^{25} = +0.72^\circ$ , the difference being  $1.85^\circ$ . For 0.025 mol, 1.8520 g., *d*-sec.butyl alcohol in 20 cc. benzene solution,  $\alpha_D^{25} = +2.60^\circ$ ; for 0.025 mol, 6.2375 g., butylchloral-*d*-sec.butylalcoholate in 20 cc. benzene solution,  $\alpha_D^{25} = +10.20^\circ$ , the difference being  $7.60^\circ$ .

As the reaction proceeds, the active alcoholate is partly converted into alcoholate of the inactive alcohol and free active alcohol, with a resulting change in the rotation. The course of the reaction can be followed

by determining graphically the percentage of free active alcohol and active alcoholate. Fig. 1 gives the curve for the rotation of mixtures of *l*-amyl alcohol and chloral-*l*-amylalcoholate; Fig. 2, that for *d*-sec.butyl alcohol and butylchloral-*d*-sec.butylalcoholate. The ordinates represent the angles of rotation and the abscissae, from left to right, the percentages of active alcohol. The curves are not linear as assumed by Kuntze.

It is to be observed that these curves were determined for solutions containing only the optically active substances, whereas in the following

experiments, where the curves were used for determining the end points of reactions, other (optically inactive) substances were present which might affect the rotations. It will be seen, however, that the absolute value of the equilibrium point of the reactions is not the matter of primary importance, but rather the order in which the end points with the different alcohols fall. The end point of the reaction cannot, in fact, be exactly determined by the method used since, on account of the high velocity of the interaction between the alcohols and alcoholates concerned, it is impossible to determine the correction to be applied to the observed rotation for the effect of all the substances in the solutions on the rotatory power of the optically active substances. It can be shown, however, that there is no reason to suspect any disturbance from this cause which

Fig. 2.

could affect the order in which the end points with the various alcohols fall. In the case of alcohols sufficiently near together in the series, so that such slight disturbances would be of consequence, the nature and concentration of the substances present is either the same, or so nearly so, that this effect upon the rotation of the active compounds present should be the same. The following tests confirm this expectation. It will be seen that the rotatory power of *d*-sec.butyl alcohol is unaffected by the

presence of other alcohols. In the case of butylchloral-*d*-sec.butylalcoholate the rotation is affected by other alcoholates, but the effect is small and is the same for the alcoholates tried.

The following experiments were carried out in 20 cc. of benzene solution at concentrations approximately the same as those occurring in the experiments below:

	$\alpha_D^{25^\circ}$
0.5 $\times$ 0.025 mol <i>d</i> -sec.butyl alcohol.....	1.28°
Upon addition of 0.5 $\times$ 0.025 mol methylisobutylcarbinol.....	1.28°
Upon addition of 0.5 $\times$ 0.025 mol methylisopropylcarbinol.....	1.28°
0.68 $\times$ 0.025 mol <i>d</i> -sec.butyl alcohol.....	1.77°
Upon addition of 0.32 $\times$ 0.025 mol ethyl alcohol.....	1.77°
Upon addition of 0.32 $\times$ 0.025 mol <i>n</i> -propyl alcohol.....	1.77°

The following experiments were carried out with a specimen of butylchloral-*d*-sec.butylalcoholate differing slightly in rotatory power from the purest product, but the similarity in effect in the two cases is unmistakable.

0.5 $\times$ 0.025 mol. active alcoholate.....	4.78°
Upon addition of 0.5 $\times$ 0.025 mol alcoholate of methylisobutylcarbinol.....	4.84°
Upon addition of 0.5 $\times$ 0.025 mol alcoholate of methylisopropylcarbinol.....	4.84°

It appears certain that, although the end point of the reaction cannot be exactly determined, the order in which the end points with the different alcohols fall must be correctly given.

Marckwald<sup>1</sup> probably obtained *l*-amyl alcohol pure, finding  $[\alpha_D^{20^\circ}] = -5.90^\circ$ . For the alcohol used here  $[\alpha_D^{20^\circ}] = -5.496^\circ$  and  $[\alpha_D^{25^\circ}] = -5.428^\circ$ , in benzene solution,  $[\alpha_D^{25^\circ}] = -5.12^\circ$ . The impurity in the *l*-amyl alcohol, a fusel oil product, is not the *d*-isomer, but chiefly isoamyl alcohol, which must be present to the extent of about 6.85%. Since isoamyl alcohol is present, it must enter into all the equilibria, but the following considerations show that its presence cannot change the order of the end points reached with the various aliphatic alcohols. Letting Chl stand for  $\text{CCl}_3\text{CH}(\text{OH})\text{O}-$ ,  $\text{R}_a$  for the active amyl radical,  $\text{R}_i$  for the isoamyl radical,  $\text{R}$  for any inactive radical; and indicating the equilibrium constants by  $\text{K}_1$ ,  $\text{K}_2$ , and  $\text{K}_3$ , and the concentrations by expressions in brackets; for the reaction,

for

and for

Hence

$$\frac{K_1}{K_2} = \frac{[\text{Chl}-R_i][R_a-\text{OH}]}{[\text{Chl}-R_a][R_i-\text{OH}]} = K_3, \text{ and } \frac{[\text{Chl}-R_i]}{[\text{Chl}-R_a]} = K_3 \frac{[R_i-\text{OH}]}{[R_a-\text{OH}]}$$

The ratio of the isoamyl- and active amylalcoholates must, therefore, remain proportional to the ratio of the isoamyl and active amyl alcohols, independently of the nature of the alkyl radical R.

*d*-Sec.butyl alcohol was also probably obtained pure by Pickard and Kenyon,<sup>1</sup> who found that  $[\alpha_D^{27}] = +13.52^\circ$  and  $[\alpha_D^{21}] = +13.85^\circ$ ; by interpolation  $[\alpha_D^{25}] = +13.63^\circ$ . For the alcohol used here  $[\alpha_D^{25}] = +13.11^\circ$ , in benzene solution,  $[\alpha_D^{25}] = +14.04^\circ$ . The impurity in the *d*-sec.butyl alcohol is probably chiefly the *l*-isomer which cannot change the order of the end points reached with the different aliphatic alcohols. If the impurity is wholly the *l*-isomer, the *d*-sec.butyl alcohol is 98.08% pure.

Table II gives a list of the aliphatic alcohols which were allowed to react with butylchloral-*d*-sec.butylalcoholate and chloral-*l*-amylalcoholate. The alcohols are arranged in order corresponding to the percentage of active alcohol set free, which is equivalent to the percentage of alcoholate of the inactive alcohols formed. In both series the first column gives the formula of the alcohol; the second column, the number of hydrogen atoms occurring in the various positions in the molecule (explained more fully below); the third column, the average observed rotations; and the fourth column, the percentage of active alcohol set free, determined graphically from Figs. 1 and 2.

### III. Discussion of Results.

It will be seen at once from the foregoing table that the three classes of alcohols fall in separate groups, as in the work of Menshutkin. Also, the change in the end point of the reaction is roughly parallel to the molecular weights of the alcohols. Since, however, there are marked exceptions to the latter statement and since isomeric compounds do not give the same values, it is necessary to look for a more exact basis for the observed relationships.

Passing down the list of alcohols in both series of experiments,  
 $\text{CCl}_3\cdot\text{CH}(\text{OH})\text{O}-\text{C}_5\text{H}_{11} + \text{R}-\text{OH} \rightleftharpoons \text{CCl}_3\cdot\text{CH}(\text{OH})\text{O}-\text{R} + \text{C}_5\text{H}_{11}-\text{OH},$   
 and

$\text{CH}_3\cdot\text{CHCl}\cdot\text{CCl}_2\cdot\text{CH}(\text{OH})\text{O}-\text{C}_4\text{H}_9 + \text{R}-\text{OH} \rightleftharpoons$   
 $\text{CH}_3\cdot\text{CHCl}\cdot\text{CCl}_2\cdot\text{CH}(\text{OH})\text{O}-\text{R} + \text{C}_4\text{H}_9-\text{OH}$

the equilibrium point is gradually shifted to the left. This must mean that the affinity of the alkyl radicals, R, for the hydroxyl group is increasing more than their affinity for the chloral group. The assumption that the affinity for negative groups is increasing in this direction is justified by the investigation carried out in this laboratory and elsewhere on the equilibrium,  $(\text{CH}_3)_2\text{CH}\cdot\text{CHBr} \rightleftharpoons (\text{CH}_3)_3\text{CBr}$ . In the gaseous condition, 18% of isobutyl bromide is in equilibrium with 82% of tertiarybutyl bromide, indicating that the radical in the latter has the greater affinity for bromine. It, therefore, appears reasonable to assume that its affinity will be correspondingly greater for any negative radical;

<sup>1</sup> *J. Chem. Soc.*, 99, 64 (1911).

i. e., that the affinity of the radicals for negative groups increases as we pass downward in the table; the increase with respect to the hydroxyl group, however, is the greater. For the sake of brevity the radicals will be called more positive as we pass downward in the table.

Since in the reactions studied different alkyl radicals are joined to oxygen both in the alcoholates and in the alcohols, the simplest assumption, in view of the affinity of hydrogen for oxygen, would be that the difference in affinity is controlled by the difference in the number and position of the hydrogen atoms in the molecule. A consideration of the results will be seen to justify this point of view.

The position of the hydrogen atoms will be designated by their relation to the carbon atom united with the hydroxyl or chloral group. Some scale must be adopted which expresses the relative influence of hydrogen atoms in different positions upon the affinity of the radical. According to van't Hoff<sup>1</sup> the total influence which two atoms in a molecule have on each other can be separated into two effects, the indirect action exerted along the carbon chain and the direct action exerted through space. Michael,<sup>2</sup> not discriminating between these two effects, uses a scale which represents the sum of the direct and indirect influences of all the atoms of a normal organic compound upon any given atom. The following scale represents the order of decreasing influence: 1-2-3-5-6-4-7-(9-10-11)-8. The carbon atom joined to the —OH radical is taken as 1 and the other atoms are numbered according to their degree of removal from carbon atom 1; thus, for example, in methylisobutylcarbinol,

It is to be noticed that according to this scale the atoms in Position 4 have relatively less effect than those in Positions 5 and 6. This assumption, among others, is tested by the results obtained in this investigation.

The alcohols were all purified with care and an examination of the results seems to indicate that none of the differences in the amounts of active alcohol displaced can be the result of impurities.<sup>3</sup> As will be seen, all the important conclusions are based on comparatively large differences.

(a) Within the first five positions the replacement of hydrogen by methyl, which introduces three hydrogen atoms into the position next further removed, always increases the positive character of the radical, so that less active alcohol is displaced. Since, however, the *primary, secondary,*

<sup>1</sup> *Ansichten über organische Chemie*, 1, 284; 2, 252 (1878).

<sup>2</sup> *J. prakt. Chem.*, N. S., 60, 331 (1899); *Ber.*, 39, 2139 (1906).

<sup>3</sup> The smallest difference could be accounted for only by over 1% of impurity, which is entirely improbable, although further work on some of the alcohols is now in progress.

and tertiary alcohols fall in three separate groups, it appears that the replacement of a hydrogen atom in Position 2, H, by a methyl group in Position 2-3, CH<sub>3</sub>, is much more effective in increasing the positive character of the alkyl radicals than any alteration in their structure and composition which leads to the replacement of H by CH<sub>3</sub>, or of H by CH<sub>3</sub>.

(b) Three hydrogen atoms in Position 4 are more effective than one in Position 3, although Position 4 is relatively weak according to the scale adopted.

Whenever H is replaced by CH<sub>3</sub> there is an increase in the positive character of the radical, less active alcohol being displaced. Examples of this are, ethyl and *n*-propyl alcohols; isopropyl and *s*-butyl alcohols; methylisopropyl- and methyl-*t*-butylcarbinols; and *t*-butyl and *t*-amyl alcohols. The differences between the end points are considerably greater in the butylchloral than in the chloral series, which is a result of the relatively greater importance of Position 4 in the former.

(c) The relatively small influence of atoms in Position 4 as compared with those in Position 5, as predicted by Michael, can be clearly seen in the chloral series. In the first place, the replacement of H by CH<sub>3</sub> is much more effective than the replacement of H by CH<sub>3</sub>. For example, the change in passing from *n*-propyl to *n*-butyl alcohol is greater than that in passing from *n*-propyl to isobutyl alcohol; from *s*-butyl alcohol to methyl-*n*-propylcarbinol greater than from *s*-butyl alcohol to diethylcarbinol; and from *t*-amyl alcohol to dimethyl-*n*-propylcarbinol greater than from *t*-amyl alcohol to diethylmethylcarbinol. Still more striking evidence of the influence of Position 5 is the fact that methyl-*n*-propyl- lies below methyl-*t*-butylcarbinol, as well as the fact that methyl-*n*-propyl- and methylisobutylcarbinols lie below methylisopropyl- and methyl-*t*-butylcarbinols, respectively. It is apparent that the position of the hydrogen atoms has a marked influence upon the positive character of these radicals and that it even outweighs the effect of difference in number of hydrogen atoms in the case of methyl-*n*-propyl- and methyl-*t*-butylcarbinols.

(d) Turning to the butylchloral series, the relative effects of atoms in Positions 4 and 5 appear in most cases to be reversed, which accounts for the most important differences in the two series. In the butylchloral series, *n*-butyl alcohol lies above *n*-propyl and isobutyl alcohols; methyl-*n*-propyl- and methylisobutylcarbinols lie above diethyl- and methylisopropylcarbinols; and dimethyl-*n*-propyl- and dimethylisobutylcarbinols lie above diethylmethylcarbinol. Evidently the spatial arrangement comes into play in some way not accounted for in the scale of influence given above. More definite conclusions can only be reached after other series of equilibria have been investigated.

(e) Looking again at Michael's scale of influence, 1-2-3-5-6-4-7-9-10-11-8-, it will be seen that atoms in Position 8 have much less influence than those in Position 7, so that  $3\text{H}$  may be less influential than H. This would account for the fact that *n*-heptyl alcohol lies above *n*-hexyl alcohol in both series. It is also evident that both Positions 7 and 8 are less effective than Positions 4 and 5 and this may partly explain why *n*-heptyl and *n*-hexyl alcohols lie higher up in both series than would be expected from their comparatively large molecular weights.

(f) Isomeric compounds have quite different end points except when they have the same number of hydrogen atoms in the same positions. The fact that isomeric compounds usually displace different amounts of active alcohol is explained by the fact that their hydrogen atoms are differently situated, as in several of the cases cited under (c) and (d). The resulting differences in the positive character of the radicals is slight, however, in the case of diethyl- and methylisopropylcarbinols, which have the same number of hydrogen atoms in the same positions. In both series the difference between the end points reached with these two alcohols is clearly less than the difference between the end point of either and that of their common isomer, methylisopropylcarbinol, whose hydrogen atoms occupy different positions. It will be noticed, however, that in the chloral series diethylcarbinol lies above methylisopropylcarbinol, whereas the order is reversed in the butylchloral series. Here, again, is evidence of spatial influences not accounted for in the scale adopted.

(g) Whether or not some specific influence of the carbon atoms comes into play can hardly be determined from the results obtained with the alcohols used in this investigation. If, however, carbon has a negative influence, it is doubtless weak as compared with the positive influence of hydrogen. Rather strong evidence of this is furnished by the fact that the replacement of H by  $\text{CH}_3$  increases the positive character of the radical even in the chloral series where Position 4 is weaker than Positions 3 and 5. If the positive character of the radical is still increased, in spite of the fact that the positive H has been replaced by negative C and three hydrogen atoms introduced into the relatively weak Position 4 it is evident that any negative influence due to the carbon must be slight as compared with the positive influence of hydrogen. Michael has considered the effect of the carbon somewhat in detail, but the results given here do not justify any further discussion.

The results may thus be to a considerable extent coördinated on the basis adopted—that the affinity of the aliphatic radicals for negative groups is governed chiefly by the number and position of the hydrogen atoms. It is possible to construct a scale which represents the relative

influence of all the atoms in the molecule, although the scale cannot be exactly the same for the two series.

As stated above, it is concluded that the affinity of the alkyl radicals for hydroxyl increases more than does that for the chloral radical as we pass downward in the table. Obviously, however, since the order of the alcohols is not the same in the two series, neither of them can be assumed to represent the relative affinity of the alkyl radicals for hydroxyl. Nevertheless it is possible that this is represented approximately by the order in either of the series. The order in which these radicals would fall as regards their affinity for the chloral and butylchloral radicals, respectively, is evidently not the same.

If we consider that this increase in the affinity of the alkyl radicals for "negative" radicals is due to increasing "positive" character of the former, it is evident that the degree of this "positive" character is not an absolute property or characteristic of any given radical, but depends upon the structure of the group to which it is joined. This is quite in keeping with the assumption that the affinity for the negative radical is controlled to a considerable extent by attractive forces between the hydrogen atoms and the oxygen or other atoms of the negative group. The position of these hydrogen atoms relative to the carbon by which the alkyl group is united to other groups—the factor chiefly considered above—may thus be in some cases of less significance than their position relative to various other atoms of the molecule. The spatial relationships involved here, as well as the other questions raised above, obviously require much further investigation. The problem, however, appears to be more fundamental and is probably simpler than that of the relation between constitution and reaction velocity.

#### IV. Molecular-weight Determinations with Chloralethylalcoholate.

Since chloralethylalcoholate was found by Beckmann<sup>1</sup> to be dissociated in benzene solutions, it was considered desirable to carry out further molecular-weight determinations at various concentrations in benzene, in order to gain information regarding the condition of the alcoholate at the concentrations at which the foregoing experiments were carried out. At the same time it appeared to be a good opportunity to investigate the behavior of such a nonelectrolytic dissociation in a variety of solvents. Brunner's<sup>2</sup> statement that no dissociation was to be found in any solvent was open to doubt in view of the dissociation known to occur in benzene.

The customary Beckmann apparatus was used, except that the stirrer was provided with a mercury seal to prevent the entrance of moisture and the evaporation of solvent. Without this it was found impossible to obtain accurate results, especially when the solutions were left standing

<sup>1</sup> *Z. physik. Chem.*, **2**, 724 (1888).

<sup>2</sup> *Z. physik. Chem. R.*, **45**, 380 (1903).

for several hours or often for a day or more. The freezing point and dielectric constants were taken from Landolt, Börnstein, and Roth Tabellen (1912).

The molecular weight of chloral itself was first determined in benzene. In a 2.5% solution by weight, the molecular weight of chloral was found to be 164 (calculate 147.4); therefore, chloral is somewhat associated in benzene solution. Since the freezing point did not alter on standing for two days, it is evident that chloral does not react with benzene in any way.

TABLE III.

Chloroethylalcoholate in benzene. Calculated molecular weight 193.4. Freezing point constant 4.9. Dielectric constant 2.288<sup>18°</sup>.

G. solute per 100 g. solvent.	$\Delta$ .	Molecular weight.	Percentage dissociation.	$K \times 10^{-4}$ .
0.15	0.044°	167	15.74%	1.99
0.37	0.109	173	11.99	2.75
0.49	0.142	174	11.15	2.79
0.59	0.166	176	9.61	2.74
0.73	0.206	178	8.41	2.56
1.07	0.295	182	6.38	2.11
1.22	0.331	186	4.21	1.13
2.04	0.543	189	2.30	0.50
5.01	1.276	197	...	...
7.90	1.974	199	...	...
9.23	2.218	208	...	...
13.46	3.026	222	...	...

It was found that the dissociation does not occur instantaneously since, in the more dilute solutions where dissociation was greatest, equilibrium was reached only after several hours, the change in the molecular weight amounting to 10% in some cases. In the solutions where association occurred equilibrium was usually reached immediately; although the value here was sometimes high at first, indicating, as would be expected, that part of the molecules were undergoing dissociation.

For solutions of concentrations 0.37, 0.44 and 0.59%, the dissociation is evidently taking place in accordance with the law of mass action. The values of the dissociation constant  $K = \frac{[CCl_3 \cdot CHO][C_2H_5OH]}{[CCl_3 \cdot CH(OH)O-C_2H_5]}$ , are in fairly good agreement, 2.74, 2.79 and  $2.74 \times 10^{-4}$ . For more concentrated solutions the value of the dissociation constant gradually decreases, which is readily accounted for by the fact that association has already begun to take place to an appreciable degree. In solutions of the concentration 5.01% association predominates. The concentrations of alcoholate in the equilibrium determinations was always considerably greater than this.

There seems to be, in general, no evidence of any definite relation between association and optical rotation,<sup>1</sup> but, in any case, since the re-

<sup>1</sup> Turner, "Molecular Association," p. 104 (1915).

sulting rotations were referred to an empirical curve any disturbance from this cause would be eliminated.

TABLE IV.

## Chloralethylalcoholate in bromoform.

Freezing-point constant = 14.4.			Dielectric constant = $4.51^{20^\circ}$ .		
G. solute per 100 g. solvent.	$\Delta$ .	Molecular weight.	G. solute per 100 g. solvent.	$\Delta$ .	Molecular weight.
0.42	$0.332^\circ$	182.6	1.54	$1.072^\circ$	208
0.44	$0.351^\circ$	183.1	5.14	$3.016^\circ$	246
1.04	$0.761^\circ$	198	5.55	$3.193^\circ$	250

## Chloralethylalcoholate in nitrobenzene.

Freezing-point constant = 7.05.		Dielectric constant = $36.45^{18^\circ}$ .	
G. solute per 100 g. solvent.	$\Delta$ .	Molecular weight.	
2.05	$0.700^\circ$	205	

## Chloralethylalcoholate in ethylene bromide.

Freezing-point constant = 11.8.		Dielectric constant = $4.86^{18^\circ}$ .	
G. solute per 100 g. solvent.	$\Delta$ .	Molecular weight.	
0.38	$0.231^\circ$	179	

In Fig. 3 the molecular weight of chloralethylalcoholate is plotted against the concentration of the solution. When extended to more concentrated solutions the curve for benzene bends upward.

Fig. 3.

It will be seen that the values of the molecular weight in bromoform are higher throughout than in benzene, although the former has a somewhat larger dielectric constant. In a 5.01% benzene solution the molecular weight is 197, whereas in a 5.14% bromoform solution it is 246. The effect of the dielectric constant is more conclusively tested by the determination of the molecular weight in nitrobenzene. It was found that chloralethylalcoholate is no more dissociated in nitrobenzene of high dielectric constant than in the solvents whose dielectric constants are comparatively

low. Table V gives a comparison of the values of the molecular weight of chloraethylalcoholate in the various solvents with their dielectric constants, the values being read from the curve in the case of bromoform.

### V. Experimental.

***l*-Amyl Alcohol.**—*l*-Amyl alcohol was dried by boiling with lime for two days and was carefully fractionated with a column of beads. B. p. 128–128.05° (760 mm.).  $\alpha_D^{25} = -4.43^\circ$ ,  $d_4^{25} = 0.8152$ ,  $[\alpha_D^{25}] = -5.428^\circ$ ;  $\alpha_D^{20} = -4.49^\circ$ ,  $d_4^{20} = 0.8169$ ,  $[\alpha_D^{20}] = -5.496^\circ$ . The rotation of the pure alcohol given by Marckwald<sup>1</sup> is  $[\alpha_D^{20}] = -5.90^\circ$ . The alcohol used here is 93.15% pure, and the impurity is doubtless isoamyl alcohol as discussed above.

***d*-Sec.butyl Alcohol.**—*dl*-Sec.butyl alcohol was prepared by the reduction of methylethyl ketone by hydrogen according to Ipatiew's method. The reduction occurred at 180–200° with nickel oxide as catalyst. *d*-Sec.butyl alcohol was obtained by the method recently described by Pickard and Kenyon<sup>2</sup> and the separation was carried out in most respects according to their description. It was found, however, (a point not noted by them) that the solubility of the brucine *s*-butyl phthalate in acetone was greatly influenced by the amount of water present. It was found necessary to add 30–50 cc. of water to a liter of acetone to bring about solution in the proportion specified by them. The brucine salt was recrystallized from methyl alcohol seven or eight times until a constant rotation was obtained for a sample containing 1 g. salt in 50 cc. absolute ethyl alcohol. The specific rotation of the salt usually obtained was  $[\alpha_D] = -4.62^\circ$ . The value given by Pickard and Kenyon is  $[\alpha_D] = -2.93^\circ$ . Since the *d*-sec.butyl alcohol proved to have a lower rotation than that obtained by Pickard and Kenyon, it is evident that a complete separation was not obtained, although the rotation of the brucine salt did not change on further recrystallization. It appears possible that the brucine used contained other alkaloids which interfered with the separation. The *d*-sec.butyl alcohol was dried with fused potassium carbonate and by boiling with lime for three days, and was then carefully fractionated with a column of beads. B. p. 98.7–99.1° (760 mm.).  $\alpha_D^{25} = +10.53^\circ$ ;  $d_4^{25} = 0.8034$ ;  $[\alpha_D^{25}] = +13.11^\circ$ . The value given by Pickard and Kenyon (obtained by interpolation between the values given for 21°

<sup>1</sup> *Ber.*, 34, 485 (1901).

<sup>2</sup> *J. Chem. Soc.*, 103, 1923 (1913).

and  $27^\circ$ ) is  $[\alpha_D^{25}] = +13.63^\circ$ . The impurity in the alcohol is probably the *l*-isomer.

**Chloral** was obtained by distilling pure chloral twice from sulfuric acid, care being taken to protect it from moisture. B. p.  $97.3\text{--}97.8^\circ$  (760 mm.).

**Butylchloral** was prepared from butylchloral hydrate, which was dehydrated by shaking with sulfuric acid in a separating funnel. The upper layer, consisting of the butylchloral, was removed and treated with powdered lime to remove any sulfuric acid which might be present, and carefully protected from moisture during the subsequent fractionation. B. p.  $164.5\text{--}165.5^\circ$  (760 mm.).

**Chloral-*l*-amylalcoholate** and **butylchloral-*d*-sec.butylalcoholate** are colorless liquids, prepared by mixing equimolecular quantities of the active alcohol and the aldehyde. Since the union is accompanied by a large evolution of heat, the liquids were cooled in ice and salt and protected from moisture as much as possible while they were being mixed.

**Chloralethylalcoholate** was recrystallized twice from benzene and dried in a desiccator. It was introduced into the solvent in the form of pellets. M. p.  $50^\circ$ .

The primary alcohols were all good commercial products, carefully dried by boiling with lime and fractionated with a column of beads.<sup>1</sup>

*Methyl alcohol*. B. p.  $64.7^\circ$ .      *n-Butyl alcohol*. B. p.  $117.55\text{--}117.95^\circ$ .  
*Ethyl alcohol*. B. p.  $78.0^\circ$ .      *n-Hexyl alcohol*. B. p.  $155.2\text{--}155.7^\circ$ .  
*n-Propyl alcohol*. B. p.  $97.1\text{--}97.4^\circ$ .      *n-Heptyl alcohol*. B. p.  $172.5\text{--}173.5^\circ$ .  
*Isobutyl alcohol*. B. p.  $107.85\text{--}107.95^\circ$ .

**Isoamyl alcohol**, from a commercial product containing 15% of active amyl alcohol, was obtained nearly pure by Marckwald's urethane process.<sup>2</sup> The alcohol was converted into its urethane which was recrystallized from ligroin. Isoamyl urethane which, is much the less soluble, was obtained very nearly free from active amyl urethane after one recrystallization. The alcohol so obtained had a specific rotation of  $[\alpha_D] = -0.048^\circ$ , thus containing about 0.81% of active amyl alcohol. B. p.  $131.2\text{--}131.6^\circ$ .

The secondary alcohols, with the exception of diethylcarbinol, were all obtained by the reduction of ketones according to Ipatiew's method. Alcohols prepared in this way always contain some ketone which can be detected by the sodium nitroprusside test. This test is sensitive to one part of acetone in 1000, but is somewhat less sensitive to the other ketones. The alcohols can be freed from ketone in either of the two following ways: by treatment with phenylhydrazine according to Michael's<sup>3</sup> method or by treatment with *p*-nitrophenylhydrazine, which has the great advantage of remaining behind during the subsequent distillation. The alcohols

<sup>1</sup> The boiling points of all the alcohols are corrected to 760 mm.

<sup>2</sup> *Ber.*, 37, 1040 (1904).

<sup>3</sup> *Ibid.*, 42, 3157 (1909).

were all carefully dried by boiling with lime and fractionated with a column of beads.

**Isopropyl alcohol** was prepared by the reduction of acetone. It was treated with *p*-nitrophenylhydrazine and gave no test for ketone. B. p. 82.5–82.7°.

***s*-Butyl alcohol** was prepared by the reduction of methylethyl ketone and treated with phenylhydrazine. It gave no test for ketone. B. p. 98.4–99.0°.

**Methylisopropylcarbinol** was prepared by the reduction of methylisopropyl ketone. The alcohol was fractionated repeatedly and gave only a slight test for ketone. B. p. 112.9–113.9°.

**Methylpropylcarbinol** was prepared by the reduction of methylpropyl ketone, obtained from acetic ester. The alcohol was given the phenylhydrazine treatment. B. p. 118.9°.

**Methylisobutylcarbinol** was prepared by the reduction of mesityl oxide, which was obtained by boiling diacetone alcohol with a trace of iodine as described by Hibbert.<sup>1</sup> The alcohol was treated with phenylhydrazine. B. p. 130–131°.

**Methyl-*t*-butylcarbinol** was prepared by the reduction of pinacoline. The alcohol was purified by freezing out twice and gave no test for ketone. B. p. 120–120.6°.

**Di-*n*-propylcarbinol** was prepared by the reduction of di-*n*-propyl ketone. The di-*n*-propyl ketone was obtained from *n*-butyric acid by the method of Senderens<sup>2</sup> by passage over thorium oxide at 400–420°. The alcohol was well fractionated and gave no test for ketone. B. p. 154–155°.

**Diisobutylcarbinol** was prepared by the reduction of diisobutyl ketone. The latter was obtained from isovaleric acid catalytically as above. The alcohol was treated with *p*-nitrophenylhydrazine. B. p. 171.4–173.4°.

**Diethylcarbinol** was prepared by the Grignard reaction from ethyl formate and ethyl bromide. B. p. 114.8–115.2°.

***t*-Butyl alcohol.** Kahlbaum's *t*-butyl alcohol was purified by freezing out twice, and then dried and fractionated.<sup>3</sup> B. p. 81.7–82.1°.

***t*-Amyl alcohol** was prepared from amylene by Wyschnegradsky's<sup>4</sup> method. B. p. 101.7–102.1°.

**Diethylmethylcarbinol** was prepared by the Grignard reaction from ethyl bromide and ethyl acetate. B. p. 122.1–122.9°.

**Dimethylpropylcarbinol** was prepared by the Grignard reaction from methyl iodide and ethyl butyrate. B. p. 122.1–122.6°.

**Dimethylisobutylcarbinol** was prepared by the Grignard reaction from acetone and isobutyl iodide. B. p. 132–133°.

## Purification of Solvents.

**Benzene** was frozen out six times, dried with calcium chloride and phosphorus pentoxide, and fractionated. B. p. 79.4°.

**Nitrobenzene** was frozen out eight times, dried with calcium chloride, and fractionated. B. p. 210.6–210.8°.

**Bromoform** was frozen out six times, dried with calcium chloride, and fractionated. B. p. 146.6–147.5°.

**Ethylene bromide** was frozen out four times, dried with phosphorus pentoxide, and fractionated. B. p. 131.2–131.4°.

## Summary.

The equilibrium point has here been determined for the reversible reaction of chloral-*l*-amyl alcoholate and butylchloral-*d*-sec.butylalcoholate, respectively, with an extended series of aliphatic alcohols, the optically active alcohol being in each case partially displaced from its combination with the aldehyde by the other alcohol. The equilibrium point of the reaction varies with the alcohol taking part in the reaction, and the order in which the alcohols fall is not the same, although nearly so, in the two series.

The significance of the results as regards the affinities between the radicals concerned is discussed, and an attempt is made to establish a relationship between the constitution of the alcohol radicals and the end point attained in the above reactions.

The degree of dissociation of chloraethylalcoholate into its constituents has been determined in benzene for a wide range of concentrations, and in bromoform, ethylene bromide, and nitrobenzene in fewer concentrations. It is dissociated in dilute solutions, associated in more concentrated ones. There appears to be no relation between the degree of dissociation and the dielectric constant of the solvent.

We take pleasure in acknowledging our indebtedness to the Warren Fund of the American Academy of Arts and Sciences for the excellent polarimeter and spectroscope which were placed at our disposal for this work.

## ON THE REACTIONS OF THE FORMAMIDINES. VI. SOME THIAZOLE DERIVATIVES.

By F. B. DAINS AND A. E. STEPHENSON.

Received June 24, 1916.

Owing to the inability of one of the authors to continue this investigation, it has been deemed best to publish the results already obtained as a preliminary paper in this special field.

It has already been pointed out<sup>1</sup> that compounds containing a methylene grouping react with ease with the substituted formamidines, giving a primary amine and the complex CHNHR in place of the H<sub>2</sub> of the methylene group, as follows:

This occurs not only in the malonic ester, acetoacetic ester and benzyl cyanide type, but also with ring compounds like the pyrazolones and isoxazolones.

In the isothiohydantoin (ketotetrahydro-thiazoles), there is found the complex  $-\text{CO}-\text{CH}_2-\text{S}-$ , which exhibits the general reactions characteristic of an acid methylene grouping, such as aldehyde, phthalic anhydride, nitroso derivatives, etc.

Such compounds should by analogy react with the formamidines; a supposition confirmed by the following experiments:

Diphenyl-isothiohydantoin (2-phenylimido-3-phenyl-4-keto-tetra-hydro-thiazole) was readily obtained by heating in alcohol solution thio-carbanilide and chloroacetic acid. Small amounts of phenyl mustard oil glycolide and phenyl thiourethan were also formed.

Molar quantities of the isothiohydantoin and diphenylformamidine were heated at 140–50° for five hours. The reaction product contained

<sup>1</sup> *Ber.*, 35, 2509 (1902); *THIS JOURNAL*, 31, 1148 (1909); 35, 959, 970 (1913).

aniline, and, in 78% yield, 2-phenylimido-3-phenyl-4-keto-5-anilidomethylene-tetrahydrothiazole,  $C_6H_5N-CO-C=CHNHC_6H_5$

This crystallizes from alcohol in the form of short, pale yellow needles melting at  $202^\circ$ .

Calc. for  $C_{22}H_{17}ON_2$ : N, 11.32%. Found: 11.50%, 11.31%.

**Hydrolysis of the Isothiohydantoin.**—10 g. of the anilidomethylene derivative, 150 cc. alcohol and 15 cc. conc. hydrochloric acid, were heated under a reflux condenser for four hours. The products isolated were (1) diphenyl urea, (2) 2,4-diketo-5-anilidomethylene-tetrahydrothiazole (m. p.  $192^\circ$ ), formed by the hydrolysis of the phenylimido group, obtained also, as will be described later, by the condensation of diphenylformamidine and the diketothiazole, (3) 3-phenyl-2,4-diketotetrahydrothiazole due to further loss of the anilidomethylene group, and (4) aniline hydrochloride.

The results thus show a progressive hydrolysis of the molecule. It is of especial interest, however, in this fact that in all the investigations of the anilidomethylene derivatives, this is the first instance noted where that grouping could be split off without complete rupture of the entire molecule.

Di-*o*-tolyl-isothiohydantoin was prepared according to the method of Wheeler and Jamieson.<sup>1</sup> It melts at  $153^\circ$  and gives a benzal derivative melting at  $182.5^\circ$ . It should be noted here that these benzal substitution products can be formed by the direct heating of the aldehyde and hydantoin without the use of any solvent or condensing agent.

Molar quantities of the thiazole and diphenylformamidine, when heated at  $140-50^\circ$  for three hours gave a 75% yield of 2-*o*-tolylimido-3-*o*-tolyl-4-keto-5-anilidomethylenetetrahydrothiazole. From alcohol, this crystallizes in pale yellow, silky needles with a melting point of  $200-1^\circ$ .

Calc. for  $C_{24}H_{19}ON_2S$ : N, 10.53%. Found: 10.44%, 10.65%.

The monosubstituted thiazoles containing a methylene group react in an analogous manner. Thus diphenylformamidine and phenylisothiohydantoin at  $150^\circ$  yielded almost quantitatively 2-phenylimido-4-keto-5-anilidomethylene-tetrahydrothiazole,  $HN-CO-C=CHNHC_6H_5$

It is almost insoluble in alcohol, chloroform, gasoline and benzene, soluble in hot glacial acetic acid, pyridine and nitrobenzene. From the latter solvent it crystallizes in lemon yellow needles melting at  $266.5^\circ$ .

Calc. for  $C_{18}H_{15}ON_2S$ : N, 14.24%. Found: 14.12%, 13.90%.

When phenylisothiohydantoinic acid,  $C_6H_5N=CNH_2-S-CH_2-COOH$ , is heated at  $150-170^\circ$  with diphenyl formamidine, the same

<sup>1</sup> THIS JOURNAL, 25, 369 (1903).

anilidomethylenephénylthiazole (m. p. 266°) is obtained. This involves both ring closure, due doubtless to the high temperature and reaction with the methylene hydrogen. Analogous results were obtained when the same thiohydantoic acid and benzaldehyde were allowed to react at a temperature of 140–50°, though for a few moments the thermometer rose to 200°. The ring was closed and there was formed 2-phenylimido-4-keto-5-benzaltetrahydrothiazole (m. p. 254°), a substance which had been previously obtained by condensing the aldehyde and thiazole in alcohol solution by means of sodium.<sup>1</sup> A similar reaction has been noted<sup>2</sup> in the case of the acetyl or benzoyl thiohydantoic acid, since when this is heated with benzaldehyde, there is formed 1-acyl-2-thio-4-benzalhydantoin.

Another type of thiazole containing a substituted amino group, the 2-methylphenylamido-4-keto-tetrahydrothiazole, was found to condense at 150° with diphenyl formamidine yielding the 2-methyl-phenylamido-4-keto-5-anilidomethylene-tetrahydrothiazole,

This crystallizes from alcohol in reddish granules melting at 180°. It is soluble in hydrochloric acid and reprecipitated by alkalis.

Calc. for  $\text{C}_{17}\text{H}_{16}\text{ON}_2\text{S}$ : N, 13.60%. Found: 13.50%.

**Diketo-thiazoles.**—The presence of two keto groups in the ring seems to have little effect, either in diminishing or increasing the reactivity of the methylene hydrogen. Thus 3-phenyl-2,4-diketo-tetrahydrothiazole was heated with diphenylformamidine at 140–50° for three hours, giving an 80% yield of 3-phenyl-2,4-diketo-5-anilidomethylene-tetrahydrothiazole. This is difficultly soluble in alcohol from which it crystallizes in pale yellow glistening leaflets with a melting point of 192–3°.

Calc. for  $\text{C}_{18}\text{H}_{12}\text{O}_2\text{N}_2\text{S}$ : N, 9.46%. Found: 9.53%, 9.59%.

As has been noted in the early part of this article, this same compound was obtained by the partial hydrolysis of the 2-phenylimido-3-phenyl-anilidomethylene derivative.

While the above was the main reaction product obtained in heating the thiazole and formamidine, there was also formed a small amount of a compound, soluble in alcohol, melting at 237° and containing 13.11% nitrogen. The data corresponds to that demanded for diphenyl urea, which might readily be formed by the action of aniline on the original thiazole.

**Condensation of an Unsubstituted Diketothiazole.**—Under the same conditions as in previous experiments, a molar mixture of diphenyl formami-

<sup>1</sup> Wheeler and Jamieson, *THIS JOURNAL*, 25, 367 (1903).

<sup>2</sup> Wheeler, Nicolet and Johnson, *Am. Chem. J.*, 46, 469 (1911).

dine and the 2,4-diketo-tetrahydrothiazole gave the 2,4-diketo-5-anilido-methylene-tetrahydrothiazole,  $\text{HN}-\text{CO}$

This is very difficultly soluble in hot alcohol from which it crystallized in almost colorless plates melting at  $233^\circ$ .

Calc. for  $\text{C}_{10}\text{H}_8\text{O}_2\text{N}_2\text{S}$ : N, 12.73%. Found: 12.96%, 13.03%.

As a matter of interest it may be noted here that experiments show that the true thiohydantoin containing a methylene group condense with the formamides giving substituted amino methylene derivatives of the type,

isomeric with the thiazole derivatives.

These investigations are being continued in this laboratory.

LAWRENCE, KANSAS.

## RESEARCHES ON PYRIMIDINES. LXXXI. SECONDARY-PYRIMIDINE-NUCLEOSIDES AND THEIR UNIQUE BEHAVIOR ON HYDROLYSIS.<sup>1</sup>

BY TREAT B. JOHNSON AND SIDNEY E. HADLEY.

Received June 28, 1916.

This is the fourth paper from this laboratory on pyrimidine nucleosides and, like those preceding it, deals with the chemistry of uracil and thymine combinations containing alcohol groupings in position 4 of the pyrimidine ring. The classification adopted namely, primary, secondary and tertiary

<sup>1</sup> The observations recorded in this paper have developed from an investigation on nucleosides which was originally started in this laboratory by Dr. Lewis H. Chernoff in 1913. The paper has been constructed from a dissertation presented by Mr. Sidney Edward Hadley to the Faculty of the Graduate School of Yale University, 1916, in candidacy for the Degree of Doctor of Philosophy.

nucleosides, applies to pyrimidine combinations containing the typical alcohol groups represented in Formulas IV, V and VI, respectively. The two primary nucleosides of uracil and thymine (IV and III) have already been synthesized and their chemical behavior investigated.<sup>1</sup> Both compounds are characterized by their stability, and they exhibit the normal behavior of primary alcohols. Neither combination is broken down by heating with acids with rupture of the carbon union in Position 4 of the pyrimidine ring giving uracil and thymine, respectively. Instead of reacting according to Equation 2 the uracil nucleoside (IV) and also the thymine nucleoside (III) interact with acids giving their corresponding alkyl salts, of which the halide (IX) is a typical representative. In other words, pyrimidine alcohols of this type react as might be predicted and do not conform in behavior to that of natural pyrimidine nucleosides like *uridine* (VII). This combination undergoes hydrolysis with acids giving uracil and a sugar.

In the light of these interesting results it was of special interest to extend our investigation of these new alcohol combinations and synthesize representatives of secondary nucleosides. Such combinations approach in constitution still closer to that assigned to natural nucleosides (*uridine*), and consequently it was important to determine whether they are less resistant to the action of acids than the primary compounds. The secondary nucleoside (V) was the first representative to be studied, and the primary object of this preliminary paper is to record a characteristic and unique transformation which this combination undergoes on hydrolysis. *It does not interact with acids, under the conditions favorable for the hydrolysis of uridine, with production of uracil and acetaldehyde.*

<sup>1</sup> Johnson and Chernoff, *J. Biol. Chem.*, **14**, 307 (1913); *THIS JOURNAL*, **35**, 585 (1913); **36**, 1742 (1914).

<sup>2</sup> Levene and La Forge, *Ber.*, **45**, 608 (1912).

In order to obtain the nucleoside (V) according to the method already applied successfully in our previous work,<sup>1</sup> it was necessary for us to synthesize first an ether of this nucleoside. The ethyl ether was the derivative selected and was prepared easily in the following manner: Ethyl  $\gamma$ -ethoxy- $\gamma$ -methylacetoacetate<sup>2</sup> (X) was first synthesized in quantity by condensing ethyl  $\alpha$ -ethoxypropionate with ethyl propionate in the presence of metallic sodium (Claisen condensation). This was then allowed to interact with thiourea when they combined smoothly, in the presence of sodium ethylate, giving the 2-thiopyrimidine represented by Formula XI. This pyrimidine was desulfurized by digestion with chloroacetic acid giving the desired nucleoside ether represented by Formula XII. This pyrimidine can be prepared easily in quantity by this method, and proved to be especially suitable for experimental study on account of its purity, crystalline character and insolubility in water. It interacted normally with bromine to give the bromopyrimidine (XIII).

We have now made the most interesting observation that this nucleoside ether (XII) reacts in a characteristic manner when digested with hydrobromic and hydriodic acids. While the ethers of the primary nucleosides, so far examined, interact normally with hydrobromic acid, forming the corresponding alkyl halides and water, this pyrimidine reacts in an entirely different manner, giving a crystalline substance free from halogen and possessing weakly basic properties. Furthermore the pyrimidine (XII) interacts with hydriodic acid giving the same product as is obtained by hydrolysis with hydrobromic acid. This is a very

<sup>1</sup> *Loc. cit.*

<sup>2</sup> Johnson, *THIS JOURNAL*, 35, 582 (1913); Chernoff, Dissertation, Yale University, 1914.

significant result. The corresponding ethers of primary nucleosides react with this acid with formation of the corresponding alkyl pyrimidines. In other words, such nucleoside combinations are reduced by this reagent as is expressed by the following equation:

The final product of hydrolysis with these halogen acids is not the pyrimidine nucleoside represented by Formula V. Ethyl bromide and ethyl iodide are formed, respectively, during the transformation, as would be expected, but at the same time a secondary reaction sets in during hydrolysis, and a quantity of carbon dioxide is evolved which corresponds to practically one-sixth of the total carbon content of the nucleoside (V). Apparently the nucleoside (V) is the primary product of the reaction, but in this case is unstable in the presence of acids and breaks down further with destruction of the pyrimidine molecule.

This characteristic product of hydrolysis has been isolated, purified and analyzed and we find that it is not identical with uracil. It does not give Wheeler and Johnson's<sup>1</sup> test for this pyrimidine. The analytical values obtained for carbon, hydrogen and nitrogen agree with those required by the empirical formula  $\text{C}_5\text{H}_8\text{ON}_2$ . In other words, we are dealing here with an unique transformation which sharply differentiates secondary from primary nucleosides. The change is accomplished by hydrolysis and may be viewed as a dissociation of the nucleoside into carbon dioxide and the hydrolytic product  $\text{C}_5\text{H}_8\text{ON}_2$  of unknown structure. The complete transformation of the nucleoside ether (XII) is expressed by the following equations:

It is an interesting fact that the compound  $\text{C}_5\text{H}_8\text{ON}_2$  and uracil ( $\text{C}_4\text{H}_4\text{O}_2\text{N}_2$ ) both contain the same percentage of nitrogen—25%.

Regarding the structure of this interesting substance  $\text{C}_5\text{H}_8\text{ON}_2$  and the mechanism of its formation from the nucleoside (V), we have not ob-

<sup>1</sup> *J. Biol. Chem.*, **3**, 183 (1907).

tained sufficient data to enable us to formulate definite conclusions. The reaction, however, is apparently a normal one and we already have obtained good evidence that the corresponding nucleoside ether of thymine (XIV) undergoes a similar transformation on hydrolysis, yielding a substance having the formula  $C_6H_{10}ON_2$ . In other words, these two

hydrolytic products are representatives of an homologous series differing in constitution by a  $\text{CH}_2$  radical. A description of our work on secondary thymine nucleoside will be given in a later paper.

A careful search of the literature now reveals the interesting fact that of the 14 known compounds<sup>1</sup> having the formula  $C_5H_8ON_2$  and the 18 conforming to the expression  $C_6H_{10}ON_2$  two agree very closely in chemical and physical properties with our unknown hydrolytic products, namely: 2-oxy-4,5-dimethylimidazol (XV) and 2-oxy-4-ethyl-5-methylimidazol (XVI), respectively.

The imidazol (XV) was first synthesized by Kunne<sup>2</sup> and it is stated by Biltz<sup>3</sup> to darken when heated at  $290^\circ$  and sublime without melting at  $300^\circ$ . Gabriel and Posner<sup>4</sup> assigned to the imidazol (XVI) a decomposition point of  $270^\circ$ . Our hydrolytic product obtained from the nucleoside (V) did not melt at  $300^\circ$  while we find that the corresponding derivative formed by hydrolysis of the pyrimidine (XIV) melts at  $268^\circ$  with decomposition. Owing to lack of time it has been impossible for us to prepare these known imidazols and compare them with our hydrolytic products. This work will be taken up just as soon as possible. Whatever constitution is to be assigned to our hydrolytic products it is apparent that we are dealing here with an unique transformation of the greatest biochemical interest. Our researches on synthetical pyrimidine nucleosides will be continued.

### Summary.

The secondary nucleoside (V) undergoes hydrolysis, when digested with hydrobromic and hydriodic acids, giving carbon dioxide and a crystalline, basic product  $C_5H_8ON_2$  of unknown constitution.

### Experimental Part.

**Ethyl  $\alpha$ -Ethoxypropionate and Ethyl  $\alpha$ -Methoxypropionate.**—These two esters, which were employed in this investigation, were prepared according to the directions of Schreiner<sup>1</sup> by the action of ethyl  $\alpha$ -bromopropionate on sodium ethylate and sodium methylate, respectively. The  $\alpha$ -bromo ester was prepared from propionic acid according to the directions given by Zelinsky.<sup>2</sup> The reactions in neither case were productive of quantitative yields of the alkoxyl esters. For example, 142 g. and 92 g., respectively, of the purified  $\alpha$ -ethoxy and  $\alpha$ -methoxy esters were obtained from 300 g. of the ethyl  $\alpha$ -bromopropionate.

**Ethyl  $\alpha$ -Methyl- $\gamma$ -methyl- $\gamma$ -ethoxyacetoacetate,  $CH_3CH(OC_2H_5).CO.CH(CH_3)COOC_2H_5$ .** **Preparation of the Ester by Application of Reformatsky's Reaction.**—This  $\beta$ -ketone ester can be prepared by application of Reformatsky's reaction, which has been modified by Johnson<sup>3</sup> and utilized for the preparation of  $\beta$ -ketone esters. Molecular proportions of ethyl  $\alpha$ -ethoxypropionate and ethyl  $\alpha$ -bromopropionate were condensed by warming in the presence of an excess of granulated zinc amalgam. There was an energetic reaction when such a mixture was warmed on a steam bath and, unless retarded, finally became so violent that it was necessary to keep at hand a cooling device to afford proper control of the reaction. After the violent reaction was over, heating on the steam bath was continued for 5–6 hours. To the syrupy liquid thus obtained ice and water were added, when a double zinc combination was precipitated. Keeping the mixture cold with ice, this was decomposed by addition of hydrochloric acid with formation of a clear oil. Ether was then added to dissolve the oil and finally sufficient sodium hydroxide was added to the ether solution to completely dissolve the zinc hydroxide and also the  $\beta$ -ketone ester present. The alkaline solution was saved and on acidifying this with hydrochloric acid, again keeping the solution cold with ice, the free  $\beta$ -ketone ester separated as a red oil. This was extracted with ether, washed with a little water and dried over calcium chloride. We obtained by this procedure 12 g. of the  $\beta$ -ketone ester (undistilled) from 70 g. of ethyl  $\alpha$ -ethoxypropionate, which corresponds to only 12% of a theoretical yield.

**Preparation of the Ester by Application of a Claisen Condensation.**—Molecular proportions of ethyl  $\alpha$ -ethoxypropionate and ethyl propionate

<sup>1</sup> *Ann.*, 197, 13 (1879).

<sup>2</sup> *Ber.*, 20, 2026 (1887).

<sup>3</sup> *THIS JOURNAL*, 35, 582 (1913).

were mixed in a dry flask connected to a return condenser. This was then heated to  $85^{\circ}$  and a molecular proportion of sodium in wire form was added in small portions at a time. Heating was then continued for 3-4 hours, when the sodium completely dissolved and a red syrupy fluid was obtained. This was dissolved in ice water and the unaltered ester removed with ether. The aqueous solution was then acidified cold with hydrochloric acid and the free ketone ester extracted with ether. This was dried over calcium chloride and finally purified by distillation under diminished pressure. We obtained from 100 g. of ethyl  $\alpha$ -ethoxypropionate 80 g. of crude ester which yielded on distillation 30 g. of the pure ketone ester boiling at  $114^{\circ}$  under a pressure of 14 mm.

Calc. for  $C_{10}H_{18}O_4$ : C, 59.36, H, 8.91. Found: C, 58.74; H, 8.79.

**Ethyl  $\alpha$ -Methyl- $\gamma$ -methyl- $\gamma$ -methoxyacetoacetate**,  $CH_3CH(OCH_3).CO.CH(CH_3).COOC_2H_5$ .—This ester was prepared by condensation of ethyl propionate with ethyl  $\alpha$ -methoxypropionate in the presence of metallic sodium. The procedure was similar to that described above. The yield of pure distilled ester in this case was 36% of the theoretical. It boiled at  $105^{\circ}$  at 14 mm. pressure.

Calc. for  $C_{10}H_{18}O_4$ : C, 57.44; H, 8.51. Found: C, 56.90; H, 8.40.

**Ethyl  $\gamma$ -Ethoxy- $\gamma$ -methylacetoacetate**,  $CH_3CH(OC_2H_5).CO.CH_2.COOC_2H_5$ .—This ester has already been described by Chernoff<sup>1</sup> who prepared it by application of Reformatsky's reaction with ethyl chloroacetate and ethyl  $\alpha$ -ethoxypropionate. We find that the ester is more easily prepared and obtained in better yield by condensing the ethyl  $\alpha$ -ethoxypropionate with ethyl acetate in the presence of sodium. The following proportions were taken: 100 g. of ethyl  $\alpha$ -ethoxypropionate, 75 g. of ethylacetate and 17 g. of sodium. We obtained 65 g. of the  $\beta$ -ketone ester boiling at  $107^{\circ}$  at 16 mm. or a yield of ester corresponding to 58% of the theoretical. Chernoff assigned to his product the same boiling point but his yield was only 6.3% of theory. In another experiment we obtained, by condensation of 30 g. of ethyl  $\alpha$ -ethoxypropionate with 30 g. of ethyl acetate, 13.5 g. of the  $\beta$ -ketone ester.

**2-Thio-4( $\alpha$ -ethoxyethyl)-6-oxypyrimidine (XI).**—This new pyrimidine is easily obtained by condensation of ethyl  $\gamma$ -ethoxy- $\gamma$ -methylacetoacetate with thiourea. The description of a single experiment will illustrate our general procedure for preparing the compound. Seventeen grams of sodium were dissolved in 300 cc. of absolute alcohol and 40 g. of thiourea then dissolved in the ethylate solution. Sixty-five grams of the above  $\beta$ -ketone ester were then added and the mixture heated on a steam bath for about 10 hours. The sodium salt of the thiopyrimidine separated. The excess of alcohol was removed by evaporation at  $100^{\circ}$  and the residue

<sup>1</sup> Dissertation, Yale University, 1914.

dissolved in water. On acidifying this aqueous solution with hydrochloric acid the above pyrimidine separated as a colorless solid. It was purified by crystallization from hot water and separated as stout prisms melting at 206–208°. The yield was 40 g.

Calc. for  $C_8H_{12}O_2N_2S$ : N, 14.00. Found: N, 14.20.

**2,6-Dioxy-4( $\alpha$ -ethoxyethyl)pyrimidine (XII).**—This pyrimidine was easily obtained by desulfurization of the corresponding sulfur compound with chloroacetic acid. Thirty-six grams of the thiopyrimidine were digested with 31 g. of chloroacetic acid in 600 cc. of water for 10 hours. The solution was then evaporated to dryness at 100°, several additions of alcohol being made near the end of the operation to aid the removal of the chloroacetic acid by esterification. The residue was triturated with cold water and the insoluble pyrimidine purified by crystallization from hot water. It separated on cooling in the form of colorless, elongated prisms which melted at 184–186°. The yield was 20 g.

Calc. for  $C_8H_{12}O_3N_2$ : N, 15.22. Found: N, 15.19.

**2,6-Dioxy-4( $\alpha$ -ethoxyethyl)-5-bromopyrimidine (XIII).**—This compound was prepared by allowing an excess of bromine to interact, at ordinary temperature, with 2,6-dioxy-4( $\alpha$ -ethoxyethyl)-pyrimidine in acetic acid. After evaporating the acid and triturating the reaction product with water this bromo compound separated in a crystalline condition. It crystallized from boiling water in flat prisms melting at 206° to a clear oil. The pyrimidine is very soluble in alcohol.

Calc. for  $C_8H_{11}O_3N_2Br$ : N, 10.65. Found: N, 10.74.

**The Behavior of 2,6-Dioxy-4( $\alpha$ -ethoxyethyl)-pyrimidine on Hydrolysis with Acids:** *The Action of Hydrobromic Acid.*—An important result that really directed our procedure in hydrolyzing this pyrimidine was our observation that carbon dioxide was given off when this pyrimidine was digested with acids. In consequence of this unexpected behavior we were obliged to hydrolyze under specific conditions in order to obtain consistent results. The method of operating, which was finally adopted as the most successful, was as follows: Five grams of the pyrimidine and 25 cc. of hydrobromic acid were heated under a return condenser at 130° in an oil bath. It dissolved almost immediately on warming, with evolution of a gas which was identified as carbon dioxide. This effervescence was continuous for about 2 hours. During this transformation ethyl bromide was also given off and condensed in globules in the condenser tube. After the evolution of carbon dioxide ceased, the heating was continued for about 3 hours longer. The resulting fluid was dark red in color and on evaporating, to remove hydrobromic acid, a semi-solid residue was obtained. In order to remove the last trace of hydrobromic acid this was triturated with alcohol and the evaporation repeated. The residue was finally triturated with a small volume of cold water when

a colorless, granular substance deposited. This was separated and purified by crystallization from hot water. It deposited in the form of plates or distorted prisms which did not melt below  $300^{\circ}$ . More of the same compound was obtained when the original aqueous extract was neutralized with ammonia. In other words the substance was slightly basic, forming a hydrobromide which underwent dissociation on treatment with water. After final purification the product did not show a definite melting or decomposition point. It always began to turn brown when heated at  $280^{\circ}$  and remained in this condition at  $300^{\circ}$ . By repeated crystallization from hot water much material was lost as the compound appeared to undergo a change by such a treatment, being transformed into a more soluble product. What was formed here, we were unable to establish with the amount of material that was available for experimental purposes. The original compound was found to contain the same percentage of nitrogen as uracil. In fact uracil was the pyrimidine looked for here if the nucleoside underwent hydrolysis with formation of acetaldehyde and ethyl bromide. The compound was not, however, uracil. It was more soluble in water than uracil and did not respond to Wheeler and Johnson's test<sup>1</sup> for this combination. It also gave no test for bromine, proving that we were not dealing with a hydrobromic acid salt.

In another experiment 4 g. of the pyrimidine were digested with 20 cc. of hydrobromic acid for 7 hours and the excess of hydrobromic acid removed by heating on the steambath. The residue was then dissolved in 130 cc. of water, decolorized by digestion with bone coal and the solution finally cooled. One and five-tenths grams of the hydrolytic product separated. This did not melt at  $300^{\circ}$  and did not respond to the characteristic test for uracil. The aqueous solution was concentrated and cooled, when a thick syrup was obtained which gave a strong test for hydrobromic acid. This dissolved easily in cold water and on adding dilute sodium hydroxide solution a crystalline substance separated which was identified as the hydrolytic product described above. A trace of ammonia was also evolved when sodium hydroxide was added in excess. The weight obtained here was 1.3 g. This was purified by crystallization from water and showed no signs of melting at  $300^{\circ}$ . The average yield of the purified hydrolytic product was equivalent to about one-fifth of the weight of the nucleoside taken.

Calc. for  $C_8H_{12}ON_2$ : C, 53.56, H, 7.14; N, 25.00.

Found: C, 54.5, 53.56, 54.0; H, 6.85, 6.66, 7.17, 7.3, 7.00; N, 24.87, 24.86.

The reaction is expressed by the following equation:

<sup>1</sup> *Loc. cit.*

driodic acid and phosphorus<sup>1</sup> was productive of results which indicated that this pyrimidine does not interact normally with this acid. Chernoff states that he did not obtain 4-ethyluracil, but a crystalline substance possessing entirely different properties. No analysis was made, but he states that the compound was purified by crystallization from water and did not melt at 280°. We have now investigated this reaction and find that the compound formed is identical with that produced by hydrolysis with hydrobromic acid. One gram of the ethoxypyrimidine was digested with 10 cc. of hydriodic acid at 140° for 3 hours. There was an evolution of carbon dioxide and ethyl iodide distilled from the solution. After completion of the reaction a little red phosphorus was introduced and the excess of acid removed by heating at 100°. A viscous residue was obtained which was dissolved in hot water, filtered and the solution allowed to cool slowly. Distorted prisms finally deposited. They turned brown when heated at 280° but did not melt at 300°. When this substance was mixed with that obtained by hydrolysis with hydrobromic acid and heated in a capillary tube there was no lowering of the melting point.

**Quantitative Determination of the Carbon Dioxide Evolved by Hydrolysis of 2,6-Dioxy-4( $\alpha$ -ethoxyethyl)-pyrimidine with Hydrobromic and Hydriodic Acids:** *Hydrolysis with Hydrobromic Acid.*—In order to determine quantitatively the amount of carbon dioxide given off during hydrolysis the operation was carried on in a specially constructed apparatus. Our procedure was to conduct a current of carbon dioxide-free air through the digestion flask (connected to a condenser) and lead it through a train of washing bulbs containing 1% hydrochloric acid, anhydrous calcium chloride and sulfuric acid. After this thorough washing, the gas mixture was then conducted through a weighed potassium hydroxide bulb where the carbon dioxide was absorbed and determined quantitatively. The analytical results obtained agreed very closely with that required by the equation given above, and were surprisingly constant when one takes into consideration that we are dealing here with a reaction which at best cannot be accurately controlled. They are in accord with the analytical values for carbon obtained by complete combustion.

**RESEARCHES ON PYRIMIDINES. LXXXII. THE SYNTHESIS OF  
 1,3-DIAMINES BY REDUCTION OF 2-MERCAPTO-  
 6-OXYPYRIMIDINES.<sup>1</sup>**

By TREAT B. JOHNSON AND A. WILLARD JOYCE.

Received July 7, 1916.

The first investigator to observe the formation of acyclic derivatives by the reduction of pyrimidines was apparently E. von Meyer.<sup>2</sup> In his early work on the determination of the constitution of "Kyanäthins," he investigated the action of sodium amalgam on 2,4-diethyl-5-methyl-6-aminopyrimidine (II), in acid solution, and showed that this pyrimidine underwent reduction with cleavage of the ring giving ammonia, propionic aldehyde and a basic oil of unknown constitution. The same products were also formed, according to him, by reduction of this pyrimidine with sodium and alcohol. So far as the writers are aware this work of von Meyer's has never been repeated and consequently the structure of this basic reduction product has never been established. The next investigator to observe a cleavage of the pyrimidine ring by reduction in alkaline solution was Byk<sup>3</sup> who reduced 4-methylpyrimidine with sodium and alcohol and showed that it was transformed into 1,3-diaminobutane. Recently, Johnson and Joyce<sup>4</sup> have contributed further data on this subject. They investigated the action of sodium and alcohol on 2-mercapto-6-chloropyrimidines and found that such combinations easily break down by reduction with the above reagents, forming 1,3-diamines.

In the light of these interesting results it was important to extend further our investigations and examine the behavior of mercaptooxypyrimidines towards alkaline reducing agents. Combinations of this type are more available than representatives of the above series and can be synthesized easily in quantity. The electrolytic reduction of oxypyrimidines has been applied with success by Tafel and his co-workers. According to these investigators 4-methyluracil<sup>5</sup> is reduced by electrolysis

<sup>1</sup> This paper and also that entitled "The Reduction of 2-Mercapto-6-chloropyrimidines" (THIS JOURNAL, 38, 1385 (1916)) were constructed from a dissertation presented by Asa Willard Joyce to the Faculty of the Graduate School of Yale University, 1916, in candidacy for the Degree of Doctor of Philosophy.

in acid solution to methyltrimethylene urea, and with partial cleavage of the ring<sup>9</sup> forming diaminobutane,  $\text{NH}_2\text{CH}(\text{CH}_3)\text{CH}_2\text{CH}_2\text{NH}_2$ . Barbituric acid<sup>1</sup> gave by reduction under similar conditions hydouracil and trimethyleneurea. These same products were formed by reduction of dialuric acid<sup>2</sup> and also oxytrimethylene urea (V), while alloxan and uramil were transformed into hydouracil. 5-Ethylbarbituric acid<sup>3</sup> reacted in a similar manner as barbituric acid, giving 5-ethylhydouracil while *veronal* (5,5-diethylbarbituric acid) underwent an abnormal change and was converted into 5,5-diethyl-4,6-dioxyhexahydropyrimidine, (VI). Einhorn and Diesbach<sup>4</sup> have shown that 2-thio-5,5-diethylbarbituric acid is reduced by the action of sodium amalgam with cleavage of the pyrimidine ring forming diethylmalonamide (VII), formic acid and hydrogen sulfide. Veronal, on the other hand, was not reduced when subjected to similar conditions.

We have now investigated the action of sodium and alcohol on six 2-mercapto-6-oxypyrimidines and one 2-thio combination, namely:

- (1) 2-Methylmercapto-6-oxypyrimidine.<sup>5</sup>
- (2) 2-Ethylmercapto-5-ethoxy-6-oxypyrimidine.<sup>6</sup>
- (3) 2-Ethylmercapto-4-methyl-6-oxypyrimidine.<sup>7</sup>
- (4) 2-Ethylmercapto-5-methyl-6-oxypyrimidine.<sup>8</sup>
- (5) 2-Ethylmercapto-1-methyl-6-oxypyrimidine.<sup>9</sup>
- (6) 2-Ethylmercapto-1,4-dimethyl-6-oxypyrimidine and
- (7) 2-Thio-4-methyl-6-oxypyrimidine.<sup>10</sup>

All of these combinations have been described in the literature, with the single exception of 2-ethylmercapto-1,4-dimethyl-6-oxypyrimidine (6). This was prepared by alkylation of 2-ethylmercapto-4-methyl-6-oxypyrimidine with methyl iodide. Its structure was established by the fact that it underwent hydrolysis with concentrated hydrochloric acid giving 1,4-dimethyluracil<sup>11</sup> and ethyl mercaptan.

<sup>10</sup> List, *Ann.*, **236**, 12 (1886).

<sup>11</sup> Johnson and Heyl, *Loc. cit.*

We now find that all of these seven pyrimidines are reduced smoothly by means of sodium and alcohol with formation of acyclic compounds. In other words, they undergo reduction with cleavage of the pyrimidine ring, giving their corresponding 1,3-diamines. These are as follows:

- (1) and (2) Trimethylenediamine,  $\text{NH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{NH}_2$ .<sup>1</sup>
- (3) and (7) Diaminobutane,  $\text{NH}_2\text{CH}(\text{CH}_3)\text{CH}_2\text{CH}_2\text{NH}_2$ .<sup>2</sup>
- (4) 1,3-Diaminoisobutane,  $\text{NH}_2\text{CH}_2\text{CH}(\text{CH}_3)\text{CH}_2\text{NH}_2$ .
- (5) 1-Amino-3-methylaminopropane,  $\text{CH}_3\text{NH}\cdot\text{CH}_2\text{CH}_2\text{CH}_2\text{NH}_2$ .
- (6) 1-Methylamino-3-aminobutane,  $\text{CH}_3\text{NH}\cdot\text{CH}_2\text{CH}_2\text{CH}(\text{CH}_3)\cdot\text{NH}_2$ .

In no case were we able to isolate an intermediate mercapto derivative of a reduced pyrimidine. The constant evolution of mercaptan during the reaction indicated the instability of such combinations when formed. The reduction of this type of pyrimidine combinations with sodium and alcohol, therefore, affords a practical method for the synthesis of 1,3-diamines. Bases of this type should be of physiological and pharmacological interest, and our method of synthesis should make available new combinations which it would be very difficult to prepare by other known methods.

Attempts to synthesize the amino ether,  $\text{NH}_2\text{CH}_2\text{CH}(\text{OC}_2\text{H}_5)\text{CH}_2\text{NH}_2$ , by reduction of 2-ethylmercapto-5-ethoxy-6-oxypyrimidine were unsuccessful. In every experiment tried the ethoxy group ( $\cdot\text{OC}_2\text{H}_5$ ) was reduced and trimethylenediamine was the final product of the reaction. That the ethoxy group is destroyed by reduction with sodium has been observed in other cases. *o*-Ethoxybenzoic acid<sup>3</sup> reacts in a manner similar to that of our pyrimidine, when reduced with sodium and alcohol, giving hexahydrobenzoic acid. 1,4-Ethoxynaphthoic acid is also transformed by reduction with sodium amalgam into tetrahydro- $\alpha$ -naphthoic acid.<sup>4</sup>

The difficulty of obtaining mono-alkylated diamines is well known and, as far as the writers are aware, no alkyl derivatives of 1,3-diamines, containing alkyl groups linked to one or both nitrogen atoms are described in the literature. Our method of synthesis enables us to obtain such combinations without difficulty. The 2-mercapto-pyrimidines easily undergo alkylation, and by reduction of the resulting alkyl derivatives with sodium and alcohol the corresponding mono-alkylated diamines are formed. Dialkylated pyrimidines like 1,3-diethyluracil (VIII) theoretically should undergo reduction with formation of symmetrically substituted amines (IX).

### Experimental Part.

**The Reduction of 2-Methylmercapto-6-oxypyrimidine with Sodium and Alcohol. The Formation of Trimethylene Diamine,  $\text{NH}_2\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{NH}_2$ .**—The 2-methylmercapto-6-oxypyrimidine used in this experiment was prepared according to the method described by Wheeler and Merriam<sup>1</sup> by the condensation of pseudomethylthiourea hydriodide with the sodium salt of ethyl formylacetate. Twenty grams of sodium (2 molecular proportions) were placed in a liter flask, connected with dropping funnel and return condenser, and a solution of 10 g. of the pyrimidine in 200 cc. of absolute alcohol allowed to drop upon the sodium. If all the sodium failed to dissolve, after the addition of this solution, the mixture was heated on the steam bath and enough alcohol added to effect complete solution. During the operation methylmercaptan and ammonia were evolved and the solution assumed a dark, reddish brown color. After complete reduction air was blown through the mixture to expel as much ammonia as possible and the solution subjected to a steam distillation. Methylmercaptan distilled over with the trimethylene diamine. The distillate was conducted into hydrochloric acid solution, and after the operation was over, the acid solution was then concentrated by evaporation under diminished pressure. The diamine hydrochloride separated from the saturated solution as colorless, prismatic crystals. It was purified by crystallization from 25% alcohol and melted with decomposition at 243–245°. The yield was 5 g. or 47% of theory.

Calc. for  $\text{C}_3\text{H}_{10}\text{N}_2\cdot 2\text{HCl}$ : N, 19.04. Found: N, 19.04, 19.02.

**The Behavior of 2-Methylmercapto-6-oxypyrimidine towards Sodium Amalgam.**—Five grams of the oxypyrimidine and 2.0 g. of sodium hydroxide were dissolved in 50–100 cc. of water. One hundred and twelve grams of 3% sodium amalgam were then added in small amounts at a time, and the solution heated until there was no evolution of hydrogen gas. During this operation there was no evolution of mercaptan or ammonia indicating that the pyrimidine ring was not reduced. The aqueous solution did not give an alkaline distillate after steam distillation. After the steam distillation the alkaline solution was acidified with hydrochloric acid and cooled, when a colorless precipitate separated. This was filtered off and crystallized from hot water, from which it separated, on cooling, in glisten-

<sup>1</sup> *Loc. cit.*

ing plates. These melted at  $197-199^{\circ}$  and were identified as the unaltered mercaptopyrimidine. Three grams of the pyrimidine were recovered here. The filtrates were evaporated to dryness, and the residue digested with 75 cc. of absolute alcohol. This solution was filtered from inorganic salts and cooled when we recovered one gram more of the pyrimidine. In other words, the mercaptopyrimidine was not reduced by the amalgam.

**Reduction of 2-Ethylmercapto-5-ethoxy-6-oxypyrimidine.**—The pyrimidine used for reduction was prepared according to the method originally described by Johnson and McCollum.<sup>1</sup> Ten grams of the pyrimidine were taken for reduction and the operation conducted under similar conditions as described in the previous experiment. The base was removed as usual by steam distillation and obtained in the form of its hydrochloride. This crystallized from hot water in the form of needle-like prisms and melted at  $243-244^{\circ}$  with decomposition. The melting point of a mixture of this salt and the hydrochloride of trimethylene-diamine melted at  $243-244^{\circ}$  proving that the two were identical. The yield of this salt in this case was 3.0 g. or 40% of theory.

Calc. for  $C_8H_{10}N_2 \cdot 2HCl$ : N, 19.04. Found: N, 19.2.

**Reduction of 2-Ethylmercapto-4-methyl-6-oxypyrimidine. The Formation of 1,3-Diaminobutane,  $CH_3 \cdot CH \cdot CH_2 \cdot CH_2 \cdot NH_2$ .**—The 2-ethyl-

mercapto-4-methyl-6-oxypyrimidine used was prepared according to the directions of Johns<sup>1</sup> by condensing pseudoethylthiourea with the sodium salt of ethyl acetoacetate. Fifteen grams were taken for reduction and the operation carried out as described in the previous experiments. Since difficulty was encountered in accomplishing a separation of the hydrochloride of the base from ammonium chloride, the mixture of the two salts was treated with a 30% solution of sodium hydroxide when the amine separated as an oil. Air was blown through the mixture to expel ammonia, and the diamine extracted with ether and dried over potassium hydroxide. The ether solution was then saturated with carbon dioxide when the carbonate of the diamine separated. This was filtered out and decomposed by treatment with an alcoholic solution of hydrochloric acid. The hydrochloride separated in the form of hexagonal prisms melting at  $169-170^{\circ}$ . According to Byk<sup>1</sup> the hydrochloride of this base melts at  $167^{\circ}$ . Tafel<sup>1</sup> assigned to it a melting point of  $170-172^{\circ}$ . The yield was 6.2 g. or 65% of the theoretical.

Calc. for  $C_4H_{12}N_2 \cdot 2HCl$ : N, 17.37. Found: N, 17.37, 17.34.

**Reduction of 2-Ethylmercapto-5-methyl-6-oxypyrimidine. The Formation of 1,3-Diaminoisobutane,  $NH_2 \cdot CH_2 \cdot CH(CH_3) \cdot CH_2 \cdot NH_2$ .**—The 2-ethylmercapto-5-methyl-6-oxypyrimidine was prepared according to the

<sup>1</sup> *Loc. cit.*

method described by Wheeler and Johnson.<sup>1</sup> Ten grams of the pyrimidine were used for reduction. The hydrochloride of the 1,3-diaminoisobutane was purified by crystallization from absolute alcohol and separated in the form of needles. They melted at 196° to a colorless oil. About 3 g. of this salt dissolves in 200–225 cc. of boiling absolute alcohol. The yield was 5 g. or 52% of theory.

Calc. for  $C_4H_{12}N_2 \cdot 2HCl$ : N, 17.37. Found: N, 17.43, 17.50.

**Reduction of 1-Methyl-2-ethylmercapto-6-oxypyrimidine. The Formation of 1-Amino-3-methylaminopropane,  $CH_3NH \cdot CH_2 \cdot CH_2 \cdot CH_2 \cdot NH_2$ .**—The 1-methyl-2-ethylmercapto-6-oxypyrimidine was prepared by the alkylation of 2-ethylmercapto-6-oxypyrimidine<sup>2</sup> with methyl iodide. The reduction was carried on as described above but in this case we obtained a poorer yield of the base. We also encountered difficulty in separating the hydrochloride from ammonium chloride. This was accomplished by repeated crystallizations from absolute alcohol and was obtained in the form of colorless plates which melted at 185–190° to an oil. The yield of crude salt was 37% of theory.

Calc. for  $C_4H_{12}N_2 \cdot HCl$ : N, 22.47. Found: N, 22.3, 22.21.

Thirty grams of 2-ethylmercapto-4-methyl-6-oxypyrimidine were dissolved in 100 cc. of an alcoholic solution containing 10 g. of potassium hydroxide. The pyrimidine dissolved readily. After cooling, 30 g. of methyl iodide were added and the mixture warmed gently until it gave no alkaline reaction. After filtering off potassium iodide the excess of alcohol was evaporated when an oil was obtained. This was extracted with ether and dried over anhydrous sodium sulfate. Calcium chloride could not be used as a drying agent as it combined with the pyrimidine. The yield was 17.2 g. This pyrimidine was purified by crystallization from ether and deposited in the form of prisms which melted at 63–64° to a clear oil. The compound is soluble in ether, benzene and alcohol and insoluble in water, alkalis and acid solutions.

Calc. for  $C_8H_{12}ON_2S$ : N, 15.21. Found: N, 15.15, 15.24.

The structure of this pyrimidine was established by its behavior on hydrolysis. When digested with concentrated hydrochloric acid ethylmercaptan was evolved and 2-oxy-1,4-dimethylpyrimidine was formed, melting at 260°.<sup>1</sup>

**Reduction of 1,4-Dimethyl-2-ethylmercapto-6-oxypyrimidine. The Formation of 1-Methylamino-3-aminobutane,  $CH_3NH \cdot CH_2 \cdot CH_2 \cdot CH_2 \cdot NH_2$ .**

<sup>1</sup> *Loc. cit.*

<sup>2</sup> Johnson and Heyl, *Ibid.*

$(\text{CH}_3)_2\text{NH}_2$ .—This transformation was accomplished by reduction with sodium and alcohol. The hydrochloride of the diamine was obtained in the form of plates melting at  $223^\circ$ . It was purified by crystallization from absolute alcohol. The salt is very soluble in water, moderately soluble in absolute alcohol and insoluble in ether and benzene.

Calc. for  $\text{C}_8\text{H}_{14}\text{N}_2\cdot\text{HCl}$ : N, 20.2. Found: N, 20.5, 20.2.

**Reduction of 2-Thio-4-methyl-6-oxypyrimidine. The Formation of 1,3-Diaminobutane,  $\text{NH}_2\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{CH}(\text{CH}_3)\cdot\text{NH}_2$ .**—The thiopyrimidine was prepared according to the directions of List.<sup>1</sup> Five grams of the pyrimidine were suspended in 100 cc. of absolute alcohol and 20 g. of sodium gradually added. Ammonia was evolved and 150 cc. of alcohol were finally added to complete the solution of the sodium. The amine was removed by distillation with steam and converted into its hydrochloride. We obtained 1.9 g. of the salt melting at  $165$ – $167^\circ$ . A mixture of this with some pure hydrochloride of 1,3-diaminobutane melted at the same temperature. The hot alkaline solution remaining after the steam distillation was filtered and neutralized with hydrochloric acid. On cooling, 2 g. of unaltered 2-thio-4-methyluracil were recovered.

**Diurea of 1,3-Diaminobutane,  $\text{NH}_2\text{CONH}\cdot\text{CH}_2\cdot\text{CH}(\text{CH}_3)\cdot\text{CH}_2\cdot\text{NH}\cdot\text{CO}\cdot\text{NH}_2$ .**—One-half gram of the hydrochloride of 1,3-diaminoisobutane was dissolved in 10 cc. of water and one gram of silver cyanate added. The mixture was then digested on the steam bath for 15–20 minutes and the silver chloride separated by filtration.\* The urea was obtained by evaporation to dryness and purified by crystallization from alcohol. It separated in the form of clusters of distorted needles melting at  $172^\circ$ .

Calc. for  $\text{C}_6\text{H}_{14}\text{O}_2\text{N}_4$ : N, 32.16. Found: N, 32.09.

**Picrate of 1,3-Diaminobutane.**—This salt crystallizes from hot water in the form of yellow needles which melt at  $240$ – $245^\circ$  with decomposition.

Calc. for  $\text{C}_4\text{H}_{12}\text{N}_2(\text{C}_6\text{H}_3\text{O}_7\text{N}_3)_2$ : N, 20.51. Found: N, 20.24.

**RESEARCHES ON THIOCYANATES AND ISOTHIOCYANATES. X.  
 THE UTILIZATION OF TETRACHLOROMETHYLMER-  
 CAPTAN FOR THE PREPARATION OF  
 ALKYL ISOTHIOCYANATES.<sup>2</sup>**

BY TREAT B. JOHNSON AND E. HEATON HEMINGWAY.

Received July 7, 1916.

Tetrachloromethylmercaptan VI, and amines combine to give representatives of an interesting class of compounds which have not been

<sup>1</sup> *Loc. cit.*

<sup>2</sup> This paper and also that entitled "Ethyl Isothiocyanacetate" (THIS JOURNAL, 38, 1550) were constructed from a dissertation presented by Earl Heaton Hemingway to the Faculty of the Graduate School of Yale University, 1916, in candidacy for the Degree of Doctor of Philosophy.

very thoroughly investigated. The chlorine attached to sulfur is the reactive halogen atom of the mercaptan, and is removed by the action of amines, giving hydrochloric acid and almost quantitative yields of sulfamides. The anilide represented by Formula VII, is a representative of the type of compounds formed. This reaction was discovered by Rathke<sup>1</sup> in 1870 and later applied by him successfully for the preparation of the sulfanilide, VII, and the corresponding *o*- and *p*-sulfotoluides. No analyses, however, were reported. With dimethylaniline, tetrachloromethylmercaptan interacts with formation of methylviolet,<sup>2</sup>

This process was patented in 1885<sup>3</sup> and the reaction applied with eleven different tertiary amines.

According to Rathke the sulfur combinations represented by Formula VII, are characterized by their behavior on heating and their action on alkalis. When subjected to the action of potash in alcoholic solution they lose a molecule of hydrochloric acid and are converted smoothly into unstable substances whose structure has never been established with certainty. Rathke suggested the two Formulas I and II, while Beilstein<sup>4</sup> expresses the constitution of these compounds according to both Formulas I and III. The second characteristic reaction is that which

(I).

(II).

(III).

takes place by application of heat. Under such conditions Rathke states that the sulfanilides break down with formation of volatile products and sulfur combinations possessing the odor of mustard oils. These latter compounds were never identified by him and, so far as we are aware, no one has established experimentally the correctness of Rathke's assumptions. The primary object of our work was to reinvestigate this reaction and determine whether sulfanilides actually undergo such an unique rearrangement.

The three sulfanilides described by Rathke were prepared by us and the sulfanilide, (VII), and *o*-sulfotoluide obtained as oils, which refused to solidify. The *p*-sulfotoluide was a solid which could be purified by crystallization without decomposition. We now find that all three of these compounds are exceedingly unstable and break down, when heated at

130–140°, with formation respectively, of two characteristic sulfur derivatives, namely, a *mustard oil*, (XII), and apparently a polymeric modification of the mustard oil, which we have represented provisionally by Formula XI. These latter products were obtained as brown, amorphous powders, which were practically insoluble in the common solvents. It is not improbable that the polymeric modification of benzoylisothiocyanate,  $C_6H_5CONCS$ , which was first described by Miquel,<sup>1</sup> is a representative of the same type of compounds and is to be represented by Formula X. Miquel writes as follows regarding this compound:

“Dersèche à l'étuve à 100 degrés, cette substance se présente sous la forme d'une poudre jaune amorphe, insipide d'une odeur faible et aromatique.”

In the case of *p*-sulfatoluide we obtained by heating this substance at 140° a yield of *p*-tolylisothiocyanate corresponding to 33% of the theoretical. In other words, we are dealing here with an unique rearrangement involving a transformation of the sulfide grouping IV, into that corresponding to a mustard oil (V).

So far as the writer is aware, combinations containing the unsaturated radical—NSC have never been prepared.

Our observation that a mustard oil (XII) is formed along with its corresponding polymeric modification (XI),\* when sulfanilides are heated, furnishes ample justification for certain assumptions regarding the mechanism of this interesting transformation. In the first place it seems probable that the change involves the formation of an unstable, intermediate compound which is highly unsaturated and secondly, that this combination is capable of transformation into either one of the end products of the reaction. Since this rearrangement involves a dissociation of the grouping —N.C.S— between S and N and a coupling of the N with C, it is evident that the intermediate compound must be cyclic in character.

The simplest expression which meets these conditions is that represented by the cycle (VIII). This compound is the same product that is formed by the interaction of a sulfanilide (VII) with alkali. An intermediate combination of this structure would be expected to be unstable at high temperatures and break down into chlorine and the free radical (IX). This then could undergo theoretically two fundamental changes, namely, either condense as a true methylene compound ( $CH_2=$ ) giving the polymer (XI), or undergo transformation directly into a mustard oil (XII) with rupture of the linking between nitrogen and sulfur. Such an explanation seems logical and the various changes are expressed by the following formulas:

<sup>1</sup> *Ann. chim. phys.*, [5] 11, 303 (1877).

### Experimental Part.

**The Action of Aromatic Amines on Tetrachloromethylmercaptan.**—According to Rathke,<sup>1</sup> tetrachloromethylmercaptan interacts with aniline, *p*- and *o*-toluidine at low temperature with formation of sulfanilides. The aniline and *o*-toluidine compounds were obtained as

oils and the *p*-toluidide described as a solid. No attempt was made to purify the compounds, however, and no analytical data were given confirming their constitution.

We have prepared these three compounds according to a common procedure which was as follows: Thirty grams of the tetrachloromethylmercaptan were dissolved in 300 cc. of ether and the mixture cooled with ice-water. Two molecular proportions of aniline (or the toluidines) were then slowly added and the mixture agitated after each addition. Aniline hydrochloride separated at once and the ether assumed a red color. After the final addition of the amine the mixture was then allowed to stand at ordinary temperature for one hour and the aniline hydrochloride separated by filtration. The ether solution was then dried over calcium chloride and the solvent finally allowed to evaporate spontaneously. When aniline was used we obtained 33 g. of the *trichloromethylsulfanilide*,  $\text{Cl}_3\text{C.SNHC}_6\text{H}_5$ , or 85% of a theoretical yield. This compound was obtained as an oil which did not solidify on standing. It cannot be purified by distillation. *Trichloromethyl-o-sulfotoluide*,  $\text{Cl}_3\text{CSNHC}_6\text{H}_4\text{CH}_3$ , was prepared and also obtained as an oil which could not be distilled without decomposition. The yield in this case was 87% of the theoretical.

**Trichloromethyl-*p*-sulfotoluide**,  $\text{Cl}_3\text{C.S.NHC}_6\text{H}_4\text{CH}_3$ .—From 40 g. of *p*-toluidine and 35 g. of tetrachloromethylmercaptan we obtained 47 g. of this sulfotoluide. It was purified by crystallization from petroleum ether and separated in the form of colorless crystals which melted at 72° to a yellow oil. At 145° this toluide decomposes with violent effervescence.

Calc. for  $\text{C}_8\text{H}_8\text{NSCl}_3$ : N, 5.4. Found: Kjeldahl, N, 5.21, 5.22.

**The Action of Alcoholic Potassium Hydroxide on Trichloromethylsulfanilides: Cyclic Dichloromethylenephénylimidosulfide (VIII).**—This sulfide has been described by Rathke<sup>2</sup> and its constitution established by a complete analysis. It was prepared by adding an alcoholic solution of potassium hydroxide to a cold ether solution of trichloromethylsulfanilide and separated in the form of prisms melting at 140°.

**Cyclic Dichloromethylene-*p*-tolylimidosulfide.**—This compound was prepared as follows: Five grams of trichloromethyl-*p*-sulfotoluide were

<sup>1</sup> *Loc. cit.*

<sup>2</sup> *Ber.*, 19, 395 (1886).

dissolved in ether and 1 g. of potassium hydroxide (one molecular proportion) added in alcoholic solution. Each drop of alkali added produced a deep red color which disappeared on shaking and potassium chloride deposited. After filtering from potassium chloride the ethereal solution was allowed to partly evaporate spontaneously and finally absolute alcohol was added to the residue, when this cyclic sulfide was precipitated. It was purified by crystallization from ether and separated in the form of colorless needles which decomposed with explosive violence when heated at  $145^{\circ}$ . This compound is soluble in alcohol and can be crystallized from this solvent without decomposition. On long digestion, however, it is gradually decomposed. Rathke<sup>1</sup> prepared this compound, but assigned to it a melting point of  $138^{\circ}$ . He did not report an analysis of his product.

Calc. for  $C_8H_7NSCl_2$ : N, 6.36. Found: N, 6.26, 6.00.

**Cyclic Dichloromethylene-*o*-tolylimidosulfide.**—This was obtained from trichloromethyl-*o*-sulftoluide by the action of potassium hydroxide. It was obtained as a solid and crystallized from ether in the form of prismatic blocks, which melted at  $112^{\circ}$  to an oil. At  $145^{\circ}$  the compound decomposes with violent evolution of gas.

Calc. for  $C_8H_7NSCl_2$ : N, 6.3. Found: N, 5.90, 5.89.

**The Behavior of Trichloromethylsulfanilides on Heating. The Formation of Phenylisothiocyanate from Trichloromethylsulfanilide,  $Cl_3CS.NHC_6H_5 \rightarrow C_6H_5NCS$ .**—Thirty-three grams of trichloromethylsulfanilide were heated in an oil bath at  $125$ – $130^{\circ}$  for one hour. Hydrochloric acid was evolved and the sulfanilide was transformed into a brown colored resinous mass impregnated with oil. This was subjected to a steam distillation and the operation continued as long as oil distilled over. After the operation was complete, this oil was dissolved in ether and dried over calcium chloride. On evaporating the ether we obtained 3.0 g. of phenylmustard oil. When this was combined with the required amount of aniline they interacted with evolution of heat, giving quantitatively symmetrical diphenylthiourea melting at  $153^{\circ}$ . A mixture of this compound and diphenylthiourea melted at the same temperature. The water solution, which collected during the distillation, was filtered from a brown solid left behind in the flask and evaporated to dryness. From this we obtained 2.5 g. of aniline hydrochloride.

The brown residue, which was insoluble in water, was dried and weighed 12 g. It was purified by washing several times with boiling ether to remove traces of oil and then dried for analysis at  $80^{\circ}$ . The compound was insoluble in all the common organic solvents and responded to a test for sulfur. It did not contain chlorine. When heated in a capillary tube it fused to a tar at  $140^{\circ}$  and then began to decompose as

<sup>1</sup> *Loc. cit.*

the temperature was raised. A nitrogen determination agreed with the calculated value for phenylisothiocyanate. Whether the following formula represents the structure of this interesting combination remains to be established.

Calc. for  $(\text{C}_7\text{H}_5\text{NS})$ : N, 10.37. Found: N, 10.37, 10.21.

**The Formation of *p*-Tolylisothiocyanate from Trichloromethylsulf-*p*-toluide,**  $\text{Cl}_3\text{CSNHC}_6\text{H}_4\text{CH}_3 \rightarrow \text{CH}_3\text{C}_6\text{H}_4\text{NCS}$ .—Forty-seven grams of trichloromethylsulf-*p*-toluide were decomposed by heating for one hour at  $110\text{--}120^\circ$ . The same process of purification was then applied as in the previous preparation when *p*-tolylisothiocyanate distilled over with the steam. We obtained 9.1 g. of this reagent, corresponding to  $33\frac{1}{3}\%$  of a theoretical yield. It boiled at  $234\text{--}238^\circ$  and combined with aniline forming symmetrical phenyl-*p*-tolylthiourea,  $\text{C}_6\text{H}_5\text{NHCSNHC}_6\text{H}_4\text{CH}_3$ .<sup>1</sup> It was purified by crystallization from alcohol and melted at  $143^\circ$ .

Calc. for  $\text{C}_{14}\text{H}_{14}\text{N}_2\text{S}$ : N, 11.57. Found: N, 11.57, 11.36.

The mustard oil was also combined with *p*-toluidine, when we obtained *sym*-ditolylthiourea<sup>2</sup> melting at  $181^\circ$ .

Calc. for  $\text{C}_{16}\text{H}_{16}\text{N}_2\text{S}$ : N, 10.95. Found: N, 10.70.

After steam distillation of the *p*-tolylisothiocyanate (above) a brown solid remained behind suspended in the water. This was separated by filtration and the aqueous solution evaporated to dryness, when we recovered 7.0 g. of *p*-toluidine hydrochloride.

The brown solid was ground to a fine powder, extracted thoroughly with ether and dried at  $100^\circ$ . It showed no signs of melting at  $270^\circ$  and was insoluble in the common solvents. A nitrogen determination indicated that we were dealing with a polymeric modification of *p*-tolylisothiocyanate.

Calc. for  $(\text{C}_8\text{H}_7\text{NS})$ : N, 9.4. Found: N, 9.0, 8.95.

**The Formation of *o*-Tolylisothiocyanate from Trichloromethylsulf-*o*-toluide,**  $\text{Cl}_3\text{CSNHC}_6\text{H}_4\text{CH}_3 \rightarrow \text{CH}_3\text{C}_6\text{H}_4\text{NCS}$ .—The decomposition of this toluide was effected by heating 19 g. of the compound for several hours at  $128^\circ$ . The very black residue which was obtained was then blown with steam as described in the two previous experiments. We obtained by this operation 3.0 g. of *o*-tolylisothiocyanate. The structure was established by the behavior of the oil towards aniline. They interacted at ordinary temperature with evolution of heat, giving *sym*-phenyl-*o*-

<sup>1</sup> Gebhardt, *Ber.*, 18, 3035 (1884).

<sup>2</sup> Maly, *Jahresbericht*, 1869, 637.

tolyl thiourea. This was purified by crystallization from alcohol and melted at 140–141°.<sup>1</sup>

**The Formation of *p*-Tolylisothiocyanate from Cyclic Dichloromethylene-*p*-tolylimidosulfide,**  $\text{CH}_3\text{C}_6\text{H}_4\text{N} \begin{array}{c} \diagup \text{S} \diagdown \\ \text{CCl}_2 \end{array} \rightarrow \text{CH}_3\text{C}_6\text{H}_4\text{NCS}$ .—The cyclic

sulfide is so explosive when heated to its melting point 145° that it is unsafe to decompose more than very small quantities at a time. Volumes of irritable gases containing chlorine are given off and a brown colored residue is left behind. Five grams of the sulfide were decomposed by heating in an oil bath at 140–145°. After the violent reaction had subsided and the mixture was cool, the residue was pulverized finely and thoroughly washed with ether and water. The ether solution was saved. The brown product was insoluble in all common organic solvents and did not melt at 270°. It was apparently identical with the product obtained by heating trichloromethylsulf-*p*-toluide. It was dried at 90°. Nitrogen determinations agreed with the calculated value for a polymer of *p*-tolylisothiocyanate. The compound contained sulfur but did not give a test for chlorine.

Calc. for  $(\text{C}_7\text{H}_7\text{NS})$ : N, 9.4. Found: N, 9.51, 9.50.

The ether solution obtained above was evaporated, when a small amount of oil was obtained which was *p*-tolylisothiocyanate. We did not obtain enough of this oil for distillation. When mixed with a few drops of aniline and the mixture warmed, there was an evolution of heat and a crystalline product formed which melted at 140–142°. It was identified as phenyl-*p*-tolylthiourea.

## THE OPTICAL ROTATORY POWERS OF SOME ACETYLATED DERIVATIVES OF MALTOSE, CELLOSE AND LACTOSE.

By C. S. HUDSON AND RALPH SAYRE.

Received July 8, 1916.

**The Rotatory Powers of the  $\beta$ -Heptacetates of Methyl Maltoside and Methyl Celloside.**—If the molecular rotations of the alpha and beta forms of tetracetyl methyl glucoside,

are denoted by  $(A + B)$  and  $(-A + B)$ ,<sup>2</sup> respectively, the molecular

<sup>1</sup> Hugershoff, *Ber.*, 36, 1141 (1903).

<sup>2</sup> Hudson and Dale, *THIS JOURNAL*, 37, 1264 (1915).

rotations of the alpha and beta forms of heptacetyl methyl maltoside may be expressed as  $(A + B')$  and  $(-A + B')$ , respectively, where  $A$  represents the rotation that is due to the terminal asymmetric carbon atom and  $B$  or  $B'$  that due to the remainder of the corresponding structures. The difference of the rotations of the alpha and beta forms of the acetylated glucosides is  $2A$ , and it has been shown in the article cited that this value is  $+53900$ , hence  $A = +26950$ . If the value of  $B'$  were known it should be possible, knowing  $A$ , to calculate the rotations of the two forms of heptacetyl methyl maltoside. A value for  $B'$  can be obtained from the observed molecular rotations of the alpha and beta forms of maltose octacetate, since this substance differs in structure from acetylated methyl maltoside only in respect to the terminal asymmetric carbon atom, which has the acetyl group in place of the methyl. The rotations of the two forms of the octacetate may accordingly be expressed as  $(A' + B')$  and  $(-A' + B')$  and their sum is  $2B'$ , which has been found to be  $+125400$ ,<sup>1</sup> or  $B' = +62700$ . Hence the specific rotation of alpha heptacetyl methyl maltoside (M. W. 650) is calculated to be  $(+26950 + 62700)/650 = +138^\circ$ , and that of the beta modification  $(-26950 + 62700)/650 = +55^\circ$ . Fischer and Armstrong<sup>2</sup> have prepared from the action of silver carbonate upon acetochloromaltose in methyl alcoholic solution a crystalline heptacetyl methyl maltoside, of m. p.  $121-122^\circ$ , but they have not recorded its rotation. By the same method Foerg<sup>3</sup> prepared the same substance, found it to melt at  $125-127^\circ$ , but did not record its rotation. Koenigs and Knorr<sup>4</sup> prepared from acetonitromaltose in methyl alcoholic solution by the action of barium carbonate and a trace of pyridine, a heptacetyl methyl maltoside of m. p.  $128-129^\circ$  and specific rotation in benzene  $+61^\circ$ . Judging from the values of the melting points, the substances are identical and probably consist of the beta form, because the acetohalogen sugar derivatives yield in general the glucosides of that series. The nearness of the recorded rotation in benzene ( $+61^\circ$ ) to that calculated for the beta modification in chloroform ( $+55^\circ$ ) also supports this conclusion, but we have considered it necessary to prepare the substance anew in order that its rotation in chloroform might be measured. The value which we find in this solvent is  $+54^\circ$ , which agrees almost exactly with the calculated rotation and proves clearly that the substance is the beta form of heptacetyl methyl maltoside. While no method is known for preparing the alpha modification, the agreement between calculation and experiment in the case of the beta form makes it very probable that the calculated value for the alpha form is not far from correct.

<sup>1</sup> Hudson and Johnson, *THIS JOURNAL*, 37, 1277 (1915).

<sup>2</sup> *Ber.*, 34, 2895 (1901).

<sup>3</sup> *Monatsh.*, 23, 48 (1902).

<sup>4</sup> *Ber.*, 34, 4344 (1901).

By precisely similar calculation the rotations of the alpha and beta forms of heptacetyl methyl celloside may be calculated, the rotation of the acetylated cellose chain B" being obtained from the rotations of the alpha and beta forms of cellose octacetate. It has been found that B" = +8800,<sup>1</sup> hence the specific rotation of alpha heptacetyl methyl celloside (M. W. 650) is written  $(+26950 + 8800)/650 = +56^\circ$  and that of the beta form  $(-26950 + 8800)/650 = -28^\circ$ . Skraup and Koenigs<sup>2</sup> have prepared from acetochlorocellose in methyl alcoholic solution by the action of silver carbonate a heptacetyl methyl celloside which melted at  $173^\circ$ , but its rotation is not recorded. We have prepared this substance in pure condition and find it to melt at  $187^\circ$  (uncorr.) and to show the specific rotation in chloroform of  $-25.4^\circ$ , which is in good agreement with the calculated value for  $\beta$ -heptacetyl methyl celloside.

**The Rotatory Powers of the  $\beta$ -Heptacetates of Maltose, Cellose and Lactose.**—If the alpha and beta forms of glucose tetracetate,

were known, it should be possible to obtain from the difference of their molecular rotations the value of the rotatory power of the end asymmetric carbon atom, and by combining this value with those for the acetylated maltose, cellose or lactose chains, to obtain the rotations of the respective heptacetates of these biose sugars. These calculations would be entirely similar in method to those just indicated. Since the alpha form of glucose tetracetate has not been described, it is necessary to base the calculations upon some other similar pair of derivatives, and we have selected the alpha<sup>3</sup> and beta<sup>4</sup> tetracetates of galactose, which have recently been carefully purified in this laboratory, and their rotations in chloroform found to be  $+141^\circ$  and  $+22^\circ$ .<sup>5</sup> If the rotation of their end asymmetric carbon atom be written A" and that of the acetylated galactose residue B", the molecular rotation (M. W. 348) for the alpha form is  $(A'' + B'')$ , for the beta  $(-A'' + B'')$ , and the difference is  $2A''$ ,  $(141 - 22)348 = +41400$ , hence  $A'' = +20700$ . Using this value, the specific rotation of alpha maltose heptacetate (M. W. 636) is calculated to be  $(+20700 + 62700)/636 = +131^\circ$ , while that of the beta modification becomes  $(-20700 + 62700)/636 = +66^\circ$ . E. and H. Fischer<sup>6</sup> prepared the beta form from acetochloromaltose and record its melting point as  $179-180^\circ$

(corr.) and its initial specific rotation in acetylene tetrachloride  $+72.6^\circ$ , rising slowly to  $76.7^\circ$ . The rise is probably due to the slow establishment in solution of equilibrium between the alpha and beta forms by the mutarotation reaction. We have prepared and purified this beta form in order to measure its rotation in chloroform. The initial product showed  $[\alpha]_D = +78^\circ$  in this solvent, but on successive recrystallizations of the material from chloroform and ether, the value slowly fell; and only after sixteen recrystallizations did it become constant, indicating that the material was the pure beta form. The specific rotation of the pure substance was  $+67.8^\circ$  in chloroform, which agrees well with the calculated value for  $\beta$ -maltose heptacetate.

The specific rotations of the alpha and beta heptacetates of cellose may be calculated in the same manner from the data already mentioned to be  $(+20700 + 8800)/636 = +46^\circ$  for the alpha and  $(-20700 + 8800)/636 = -19^\circ$  for the beta modification. The cellose heptacetate which Fischer and Zemplen<sup>1</sup> prepared from iodo-acetyl cellose melted at  $195-197^\circ$  and showed  $[\alpha]_D = 20^\circ$  in chloroform. We have prepared this substance from acetobromocellose, and obtained  $+18^\circ$  for the rotation of the crude substance; but on crystallization the value gradually became lower without, however, becoming constant before the supply of material was exhausted. After eighteen recrystallizations the value was  $-2^\circ$ , which is  $17^\circ$  from the calculated value, but it seems reasonable to suppose that further purification would bring the values nearer.

The specific rotations of the alpha and beta forms of lactose heptacetate may be calculated from  $A'' = +20700$  and  $B'' = +16600$ , which is the value for one-half the sum of the molecular rotations of the alpha and beta octacetates of lactose,<sup>2</sup> to be  $(+20700 + 16600)/636 = +59^\circ$  for the alpha, and  $(-20700 + 16600)/636 = -6^\circ$  for the beta form. We have prepared lactose heptacetate, which does not appear to have been crystallized previously, by the action of silver carbonate on acetobromolactose in acetone solution. As in the case of cellose heptacetate, the amount of material available was not sufficient for completely purifying the beta form. The crude product, rotating  $+12^\circ$  in chloroform, was recrystallized twenty times, yielding a substance of rotation  $-0.3^\circ$  in chloroform, which is about  $6^\circ$  higher than that calculated for  $\beta$ -lactose heptacetate. Since the rotation has not yet reached a constant value, it is to be supposed that further purification would have made the agreement closer.

#### Experimental.

**Purification of Heptacetyl Methyl Maltoside.**—The acetobromomaltose used was prepared by the method of Dale,<sup>3</sup> which consists in treat-

<sup>1</sup> *Ber.*, 43, 2539 (1910).

<sup>2</sup> Hudson and Johnson, *This Journal*, 37, 1270 (1915).

<sup>3</sup> *This Journal*, 37, 2745 (1915).

ing the sugar with a saturated solution of hydrobromic acid in acetic anhydride. The compound could not be made to crystallize, but the amorphous sirup obtained by adding petroleum ether to its chloroform solution was sufficiently pure for our purpose. The replacement of bromine by the methoxy group was carried out in the usual manner by boiling the methyl alcoholic solution of the bromo compound under a reflux condenser with an excess of freshly prepared silver carbonate. The heptacetyl methyl maltoside was purified by recrystallization from 95% alcohol until its rotation became constant. The pure substance melted at  $125^{\circ}$  (uncorr.). A chloroform<sup>1</sup> solution containing 1.5781 g. in 50 cc. solution rotated  $6.75^{\circ}$  to the right in a 4 decimeter tube, hence  $[\alpha]_D^{20} = +53.5^{\circ}$ . A duplicate measurement, using 3.0005 grams in 50 cc., gave  $[\alpha]_D^{20} = 53.8^{\circ}$ .

**Purification of Heptacetyl Methyl Celloside.**—Part of the acetobromocellose employed was made from cellose by the action of acetic anhydride saturated with hydrobromic acid; the remainder was prepared by dissolving the octacetate of cellose in glacial acetic acid saturated with hydrobromic acid, in accordance with the directions given by Fischer and Zemplén.<sup>2</sup> The bromo compound is easily obtained crystalline and in good yield by either method. The preparation and purification of the acetylated methyl celloside was carried out in precisely the same way as that followed in making the heptacetyl methyl maltoside. The pure substance melted at  $187^{\circ}$  (uncorr.). A chloroform<sup>1</sup> solution containing 1.4962 grams in 50 cc. solution rotated  $3.00^{\circ}$  to the left in a 4 decimeter tube, hence  $[\alpha]_D^{20} = -25.1^{\circ}$ . A second measurement, using 3.0588 g. in 50 cc., gave  $[\alpha]_D^{20} = -25.7^{\circ}$ .

**Purification of Maltose Heptacetate.**—The sirupy acetyl bromomaltose was dissolved in acetone and shaken for several hours with freshly prepared silver carbonate. As soon as the bromine had been completely replaced, the silver salts were filtered off, and the acetone solution was evaporated under low pressure until crystallization occurred spontaneously. The mother liquor from this crystallization yielded a further quantity of crystals on the addition of ether. The material was recrystallized by adding ether to its chloroform solution. The specific rotation was lowered by sixteen recrystallizations from  $+78^{\circ}$  to the constant value  $[\alpha]_D^{20} = +67.8^{\circ}$  in chloroform.<sup>2</sup> The pure substance melted at  $181^{\circ}$  (uncorr.). Mutarotation occurs in chloroform, the rotation rising in about five weeks to the value  $+110^{\circ}$ ; a drop of dilute ammonia added to the solution brings the mixture to the same equilibrium in a few hours. The initial rotation of the pure substance in acetylene tetrachloride was found to be  $+65.0^{\circ}$ , rising slowly to  $+95.4^{\circ}$ . As acetyl determinations

<sup>1</sup> Chloroformum Purificatum, U. S. P.

<sup>2</sup> *Ber.*, 43, 2537 (1910).

do not appear to have been made on any of the heptacetates of the disaccharides, we hydrolyzed two half-gram portions of the pure compound with  $N/4$   $H_2SO_4$  and found 46.82 and 47.23%  $CH_3CO$  in comparison with 47.36%, the theoretical value.

**Purification of Cellose Heptacetate.**—The method used for preparing cellose heptacetate was in every way similar to that for the corresponding maltose derivative, except that the former did not crystallize spontaneously from acetone solution. Crystallization took place almost immediately, however, on adding ether after distilling off most of the acetone. The substance was recrystallized eighteen times by adding ether to its solution in chloroform, whereby the melting point was raised from  $195^\circ$  to  $204^\circ$  (uncorr.), and the specific rotation in chloroform<sup>1</sup> was lowered from  $+18^\circ$  to  $-2.4^\circ$ , without, however, reaching a constant value. The compound mutarotates in chloroform, the rotation of the equilibrium mixture being  $+22.6^\circ$ . Two half-gram portions of the substance rotating  $+5^\circ$  showed, on analysis, 47.56 and 47.67%  $CH_3CO$ ; theoretical, 47.36%.

**Preparation of Lactose Heptacetate.**—Acetobromolactose was prepared in crystalline form by treating lactose with a saturated solution of hydrobromic acid in acetic anhydride. The acetone solution of the bromo compound was shaken with freshly prepared silver carbonate until a few drops filtered from the mixture and diluted with water gave no precipitate with silver nitrate solution. The silver salts were then filtered off and the filtrate evaporated to a thick sirup under diminished pressure. At first considerable difficulty was encountered in crystallizing the heptacetate, but we have found that if the acetone solution is evaporated to a sufficiently high concentration, the addition of several times its volume of ether invariably causes crystallization in a few minutes. The yield of crude product is about 60-70% of the weight of sugar taken. The substance can be recrystallized without difficulty by adding ether to its chloroform solution, and if the amount of ether added is relatively small, the compound comes out very slowly in beautiful transparent prisms, often half a centimeter in length. Twenty such recrystallizations lowered the specific rotation in chloroform<sup>1</sup> from  $+12$  to  $-0.3^\circ$ , although even then a constant value was not reached. The purest material obtained melted at  $83^\circ$  (corr.). In its general properties, lactose heptacetate closely resembles the corresponding compounds of maltose and cellose, although it is considerably more soluble than either in alcohol, acetone and chloroform. Like them, it mutarotates in solution, the rotation in chloroform rising to  $+52.8^\circ$ .

The substance was identified as a lactose derivative by saponification with alcoholic potash, the resulting sugar being recognized as lactose by its rotatory power in water.

<sup>1</sup> Chloroformum Purificatum, U. S. P.

On combustion 0.1628 and 0.2025 g. subs. yielded 0.2913 and 0.3659 g.  $\text{CO}_2$  and 0.0863 and 0.1059 g.  $\text{H}_2\text{O}$ , corresponding to 48.8 and 49.2% C and 5.93 and 5.85% H. Calc. for lactose heptacetate ( $\text{C}_{28}\text{H}_{34}\text{O}_{18}$ ): 49.3% C and 5.70% H.

An acetyl estimation was made by boiling two half-gram portions for four hours with 100 cc.  $N/4$   $\text{H}_2\text{SO}_4$  in a quartz flask with a quartz reflux condenser, yielding 47.05 and 47.45%  $\text{CH}_3\text{CO}$  in comparison with the theoretical value, 47.36%.

## THE QUANTITATIVE DETERMINATION OF MORPHINE IN THE VARIOUS ORGANS WHEN INJECTED INTO CATS AND RABBITS.

By A. W. HOMBERGER AND J. C. MUNCH.

Received May 6, 1916.

During the past few years one of the authors has had submitted to him, at different times, organs from cadavers for the analysis of poisons—especially morphine and opium. In two cases, the suspects had been embalmed. In one case after seven days, and in the other after fifteen days, of interment, the liver, kidneys, stomach and spleen were brought for examination. The quantitative relations as well as the general chemical conduct of the alkaloids found in the different organs, raised the question as to whether this was due to the embalming fluid, or whether the length of time after burial were the cause of the fluctuating assimilation and distribution.

The following paper deals with a series of experiments carried out on cats and rabbits in order to find, if possible, what the effect of the embalming would be on the amount of alkaloid in the different organs in case death had resulted from alkaloid poisoning, to ascertain how much of the original product could be recovered under those conditions, and to find what organs might be the strongest assimilators of such alkaloids. The alkaloid used in this case was morphine.

The morphine used in these investigations was Merck & Company's "Morphinae Sulphas," U. S. P. VIII. Qualitative examination showed it to be free from foreign materials such as starch or other opium alkaloids. Quantitative determinations of the morphine present, by Mayer's Reagent, and determinations of the sulfuric acid present, as barium sulfate, showed that the morphine sulfate used agreed with the formula

The desired amount of morphine sulfate was weighed out on an analytical balance, dissolved in distilled water and hypodermically injected into the mesenteric circulation. After a lapse of three hours, to allow for fixation in the organs of the body, the animals were chloroformed

and embalmed by cavity and arterial injection of a formaldehyde embalming fluid.

When the bodies were opened for analysis, the organs were always removed in the same order, first the stomach and intestines together, then, in order the spleen, liver, lungs, heart, kidneys, bladder and urine, and finally the brain. Then any parts wanted for qualitative analysis were cut out. Analyses were commenced at once to avoid any changes due to further decomposition.

Autenrieth's<sup>1</sup> modification of the Stas-Otto process was used, with several variations, for all the quantitative extraction of the organs. A longer time of extraction (five hours),<sup>2</sup> three extractions with ether in both acid and sodium hydroxide solution, and Pückner's technic of final extraction by hot amyl alcohol in slightly ammoniacal solution were used. The extracted morphine was dried at 60°, and calculated to its equivalent weight of morphine sulfate. Titrations of this residue agreed, within the limits of experimental error, with the gravimetric results obtained above. Qualitative tests of all residues were made to prove that the extractions were complete.

Dragendorff's<sup>3</sup> method was used for the analyses of both blood and urine. Puckner's<sup>4</sup> precautions were again followed. The extracted morphine was calculated to morphine sulfate, as in the Autenrieth extraction above. The weights in the following table are all expressed as morphine sulfate,  $(C_{17}H_{19}NO_3)_2 \cdot H_2SO_4 \cdot 5H_2O$ .

As may be noted in the table, the urine contains the largest single amount found in cats. The organs may be ranked according to morphine content, as the liver, kidneys, spleen and stomach. The urine content shows a great fluctuation, which is explained by Magnus<sup>5</sup> by the great variation in urinary secretion in animals, due to various factors such as quantity of food and water consumed, fecal excretion and animal idiosyncrasy. The appearance of morphine in the stomach of a cat following hypodermic mesenteric injection, is a matter of interest. Although only a small quantity is present, its constant appearance is similar to the case of arsenic, which, irrespective of the mode of introduction, always appears in the stomach. The constancy of results in the spleen extraction is important, the spleen of all organs, in both cats and rabbits, being subject to least variation in morphine content.

The results of extraction from rabbits are subject to less fluctuation during the course of the experiments, than with cats during the corresponding period. Arranged in order of morphine content, the results rank

as kidneys, liver, urine, spleen and stomach. Rabbit "E" differed from the others, in that it received a larger dose of morphine, and was not embalmed. That the urine contains the greatest quantity of morphine agrees entirely with the results of Van Kaufmann-asser,<sup>1</sup> of Van Ryn,<sup>2</sup> and of Dorlencourt,<sup>3</sup> drawn from the analyses of rabbits killed with morphine.

<sup>3</sup> *Compt. rend.*, 56, 1338.

yses, part of it combines with some cell constituent, forming a compound which is relatively more resistant to decomposition than is the uncombined morphine. Decomposition of the organ produces chemical compounds which break up the "free" morphine, but do not appreciably affect the "combined" morphine. This decomposition and removal of morphine produces the "preliminary drop" in morphine content observed.

The fairly constant results obtained between the close of this period and the beginning of the "secondary drop" represent the results of analyses made after the "free" morphine had been disintegrated, but before conditions were such that the "combined" morphine would be affected. This period of time is fairly constant for all the animals studied.

The gradual disintegration of the "combined" morphine, starting when conditions became favorable, would account for the "secondary" drop in morphine content. This decomposition would probably lead to complete removal from the body of all morphine as such.

This conclusion is best shown by the kidneys and liver, while the constant results for the spleen would seem to indicate that all the morphine deposited in that organ was present during decomposition as "combined" morphine, which began decomposition at the same time as the "combined" morphine of the other organs.

### Summary.

From the preceding work the following conclusions may be drawn:

(1) By means of a five-hour extraction, and three extractions with ether in both acid and sodium hydroxide solution, Autenrieth's modification of the Stas-Otto process is capable of yielding 97.5% of the morphine injected into an animal, if analysis be started very soon after death.

(2) The presence of formaldehyde as embalming fluid, has no appreciable effect upon the extraction results.

(3) The loss of morphine from a cadaver proceeds in two stages, a preliminary drop due to the splitting up of the "free" morphine present, then a period during which the morphine content is fairly constant, followed by a secondary drop, due to the splitting up of the "combined" morphine, *i. e.*, that morphine which had combined with some cell constituent, thus escaping the preliminary decomposition.

(4) The "secondary" decomposition is greatly retarded by embalming, although there seems to be no effect on preliminary disappearance.

(5) Results of analyses of cats and rabbits which have received hypodermic injections of morphine, embalmed and subsequently analyzed, may be interpreted successfully by this theory of "combined morphine."

No. 273.]

## ON THE PRODUCTS OF THE ACTION OF CERTAIN AMYLASES UPON SOLUBLE STARCH, WITH SPECIAL REFER- ENCE TO THE FORMATION OF GLUCOSE.

By H. C. SHERMAN AND P. W. PUNNETT.

Received June 22, 1916.

Probably the first recognized case of what we now know as enzyme action was the observation by Kirchhoff (1814), confirmed and amplified by Dubrunfaut (1823) and by Payen and Persoz (1833), that a substance contained in barley malt is active in hydrolyzing starch with the production of reducing sugar. The sugar thus formed was for some time assumed to be glucose but later was shown by O'Sullivan<sup>1</sup> to be, at least chiefly, maltose. During the forty years since the publication of O'Sullivan's work several investigators have studied the kinds and amounts of products formed by the action of this and other amylases, but with widely varying results. The evidence as to the formation of glucose as a digestion-product of malt extract or pancreatic juice, for example, is conflicting<sup>2</sup> and among those who accept the affirmative evidence there is no apparent consensus of opinion as to whether the formation of glucose is due to the action of amylase or of a maltase simultaneously present. The general tendency to regard enzyme action as very highly specific has naturally favored the latter assumption and there has been no adequate evidence of the formation of glucose directly by amylase because in the work previously published on this subject the amylolytic agents used have been natural secretions, extracts, or simple alcohol precipitates which might have contained other enzymes along with the amylase. A reinvestigation of the question of the formation of glucose by the action of amylase was therefore undertaken.

### Methods and Results.

The general plan of the present work was to allow pancreatic and malt amylases and the amylase of *Aspergillus oryzae*—chosen as representative

of the starch-splitting enzymes of the higher animals, higher plants, and fungi, respectively—to act upon soluble starch under comparable and carefully controlled conditions, and then to examine the digestion products for glucose both by means of the osazone reaction and by quantitative measurements of reducing and rotatory powers.

The enzymes have been used both in their commercial forms and after laboratory purification and, in general, have been allowed to act in the presence of such amounts of salt and phosphate as had been found in previous tests in this laboratory to be favorable to the action of each of these amylases. The ratios of enzyme to substrate usually approximated those with which we have to deal in determinations of diastatic power or in such studies of these enzyme hydrolyses as have been described in previous papers.<sup>1</sup> In all cases the temperature at which the enzyme was allowed to act was 40°.

The experiments here described were carried out in two series—the first in 1912, the second in 1914–15.

**Series of 1912.**—In the experiments of this first series, carried out with the coöperation of Mr. David F. Renshaw, attention was chiefly devoted to the evidence to be obtained by application of the osazone reaction. The previous work in this laboratory regarding the influence of concentration of glucose and presence of maltose<sup>2</sup> was supplemented by the following observations: Using 0.4 g. of freshly purified phenylhydrazine hydrochloride with 0.6 g. of sodium acetate in a volume of 4 cc. it was found possible to obtain recognizable osazone from 10 mg. of glucose, after one hour's heating in the boiling water bath; but in the presence of several times its weight of maltose the glucose reacted much less readily.

When the amount of sodium acetate was increased to 0.8 g. (for 4 cc. of the test solution) the test appeared to be improved; this amount was therefore used in all subsequent experiments.

On applying the test to mixtures of glucose and maltose totaling 0.20 g. (the "standard" weight of sugar for the application of the osazone test in a volume of 4 cc.) the following results were obtained:

Percentage composition of sugar mixture, Glucose.....	10	9	8	7	6	5	4
Maltose.....	90	91	92	93	94	95	96
Minutes of heating for appearance of glucosazone.....	17	22	26	30	33	51	60

These results indicate the possibility of detecting by this application of the osazone test as little as 4% of glucose in a mixture of glucose and maltose alone, and of roughly judging the amount of glucose when present in somewhat larger proportion in such a mixture.

Dextrin was found to cause a marked retardation, even when present

<sup>1</sup> THIS JOURNAL, 32, 1073, 1087; 33, 1195; 34, 1104; 35, 1617, 1784, 1790; 37, 623, 643, 1305.

<sup>2</sup> Sherman and Williams, *Ibid.*, 28, 629 (1906).

to the extent of only 10% of the total carbohydrate, and if in excess of that proportion, it rendered the formation of the glucosazone very uncertain. Since it was to be expected that the mixtures of digestion products obtained by amylase action at 40° would contain at least 10% of dextrin, and probably 20% even when the action was long continued, it appeared impossible to use the digestion mixtures directly for the osazone tests. Two methods for removing the dextrin were suggested by work of previous investigators—to precipitate the dextrin by pouring the solution into alcohol; or to evaporate the solution to dryness and extract with alcohol. The precipitation method did not give good results when tried on known mixtures of glucose, maltose and dextrin—possibly because of adsorption of glucose by the precipitated dextrin or because of partial solubility of the dextrans in the alcohol solution. The second method proved better; practically no dextrin was extracted by the alcohol, and the relative solubility of glucose in hot 95% alcohol (about five times that of maltose according to Lippman), made possible the extraction of most of the glucose by the use of small amounts of the solvent. The procedure, as finally worked out, was as follows:

The digestion mixture, which had been kept at 40° for the required time, was heated to boiling to stop the enzyme action and (usually after the determination of the rotatory and reducing powers) was evaporated to dryness on a water bath with the addition of some clean sand to render the mass more porous and facilitate its subsequent extraction. The dry mass of carbohydrates, salts and sand was then boiled for two minutes, with constant and vigorous stirring with 20 cc. of 95% ethyl alcohol. The alcohol extract was decanted off while hot and evaporated to dryness on the water bath. The sugar thus extracted was weighed and dissolved in twenty times its weight of water and 4 cc. of this solution used for each osazone test. If the digestion has been long continued, about 10–15% of the mass is extracted in this way. If the starch conversion is very incomplete, it is generally necessary to repeat the extraction process in order to obtain a sufficient quantity of reducing sugar for satisfactory testing.

This method was applied to the digestion products resulting from the action of the following amylase preparations: (1) a high grade commercial pancreatin powder furnished by Parke, Davis and Company; (2) a highly purified and very active preparation of pancreatic amylase made in this laboratory; (3) malt amylase preparations purified in the laboratory but not representing as high a degree of activity as was reached later; (4) a preparation, kindly furnished us by Dr. J. Takamine, which contained the amylase of *Aspergillus oryzae* and showed about four times the diastatic power of ordinary commercial takadiastase. In all of these cases the sugar extracted from the digestion mixture gave an osazone reaction for glucose when tested as above described. In nearly all cases, however, the reaction was very slight. Only in the extract from the products of long-continued (18 hours) action of taka diastase (containing the amylase of *Aspergillus oryzae*) was there indication of one-tenth as much glucose as maltose.

Several different samples of commercial pancreatin were allowed to act upon soluble starch for 39 hours at  $40^{\circ}$  and the digestion products then tested as above described. In all of these cases the osazone reaction gave evidence of glucose.

**Series of 1914-5.**—In this second series of experiments the enzymes were used in such concentrations as to be as nearly as practicable equivalent in amylolytic power, the quantity of enzyme preparation employed in each case being such as would digest the starch present to disappearance of blue or violet color-reaction in 30 minutes. Activating salts were used as in the first series, and the general arrangement of the experiments was the same as before, the digestion products being evaporated on sand and extracted with alcohol. Special attention was devoted to the purification of the water and salts used. Digestions were conducted at  $40^{\circ}$  and usually for 24 hours—48 times as long as was required for the digestion of the starch to products giving no blue or violet color with iodine. The reducing and rotatory powers of the organic solids of the digestion mixture and of its alcohol extract were determined, and compared with those of pure maltose. A higher reducing power or lower rotatory power than would be shown by an equal weight of pure maltose was taken as evidence of the presence of glucose in the solids extracted by the 95% alcohol from the evaporated digestion mixture (for if any dextrin had been extracted the effect would have been to alter each of these properties in the opposite direction).

The procedure for each experiment was as follows: A quantity of soluble starch, usually equivalent to 8 g. of dry matter, was dissolved in pure boiling water and, after the addition of the measured amount of the salts necessary to give the proper concentration of activator in the final solution, the solution made up to such a volume as, after the subsequent addition of the required amount of enzyme solution, would give a starch concentration of 2% in the digestion mixture. The flask was then immersed in the constant temperature bath until it had reached  $40^{\circ}$ , after which the enzyme solution was added, the flask stoppered with a plug of cotton and left in the bath for 24 hours.

At the expiration of this time it was removed, boiled to stop the enzyme action and filtered to remove the small amount of suspended matter. Considerable difficulty was experienced in this filtration. The best method was found to be by the use of Gooch crucibles containing thin pads of washed asbestos. By using three such crucibles in rotation it was possible to filter 400 cc. of solution in a few hours. This insoluble suspended matter always amounted to about 1% of the weight of the starch.

The filtered solution was often greater than the required volume and the subsequent evaporation usually produced a gelatinous precipitate, of a few milligrams weight, which was also filtered out.

The filtered solution was then made up to volume and an aliquot portion (one-tenth) was withdrawn for use in the determination of rotatory and reducing powers. Another such portion was evaporated to dryness on a water bath in a weighed glass evaporating dish containing some ignited, clean sand and then dried to constant weight by heating at  $70^{\circ}$  under a reduced pressure of 40 to 100 mm. This weight of

material corrected for the weight of enzyme and of dry activator gave the total soluble carbohydrates.

The remaining four-fifths of the solution was also evaporated on the water bath, with the addition of sand. This mixture of carbohydrate, activating salt and sand was next extracted on the water bath with boiling 95% alcohol in 20 cc. portions. The alcohol extract was evaporated to dryness, dissolved in water, and made up to a volume of 100 cc. with filtration if necessary. Ten cc. of this solution were withdrawn and used for the determination of solids as in the case of the original solution. The rotatory and reducing powers were determined as described above.

The residue left with the sand after the alcohol extraction was dissolved in hot water, filtered, and made up to 250 cc. Fifty cc. (or sometimes 25 cc.) were used for the total-solids determination and the rotatory and reducing power determined on a portion and calculated to the basis of dry carbohydrate material.

Finally the remainder of the extract solution was evaporated until each cubic centimeter contained 0.1 g. of carbohydrate and 2 cc. of this solution used in each osazone test—using 0.3 cc. of pure phenylhydrazine, 0.2 cc. of 87% acetic acid (equivalent to the phenylhydrazine base), 0.3 g. of sodium acetate, 2.0 cc. of sugar solution and 1.5 cc. of water, giving a total volume of 4 cc.

### Summary of Results.

**Pancreatic amylase** tested both in the form of commercial pancreatin and as a highly active purified preparation made by Miss M. D. Schlesinger from this same pancreatin as previously described<sup>1</sup> resulted in an extract having greater reducing power than pure maltose which, as explained above, is taken as evidence of the presence of glucose. The osazone reaction for glucose was negative in all of these extracts, indicating that the yield of glucose was small as compared with the large amount of maltose produced. The close agreement of results obtained from the action of the commercial pancreatin and of the purified amylase made from it suggests that such glucose production as occurs is attributable to the action of the amylase rather than of a separate enzyme (maltase); for it is hardly reasonable to suppose that a maltase, present as a separate substance in the pancreatin, would have remained with the amylase in unchanged ratio throughout the purification process.

**Malt amylase** was tested in the form of a purified preparation<sup>2</sup> and parallel experiments were made with malt extract. The measurements of reducing and rotatory powers of the sugars extracted as above described indicated that, along with a large amount of maltose, a small proportion of glucose had been formed both by the malt extract and by the purified malt amylase. The osazone tests for glucose were negative in these cases, the amount of glucose in the digestion mixture being too small to be demonstrated by this test, even as applied to the solids obtained by alcohol extraction.

<sup>1</sup> Preparation 62 II made as described by Sherman and Schlesinger (*THIS JOURNAL*, 34, 1105 (1912)) and showing a diastatic power of 3313, equivalent to about 5000 on Lintner's scale.

<sup>2</sup> Preparation 111A. Sherman and Schlesinger, *THIS JOURNAL*, 37, 648 (1915).

It thus appears that both pancreatic and malt amylases, even when highly purified, are not limited to the formation of maltose but may form some glucose as well; but that under conditions such as obtained in the determination of diastatic power the proportion of glucose formed is so minute as to be practically negligible in comparison with the much greater amounts of maltose formed.

**Takadiastase** and the partially purified **amylase of *Aspergillus oryzae*** prepared from it by Dr. A. P. Tanberg,<sup>1</sup> when tested in a manner parallel to the experiments with pancreatic and malt amylases just described, produced a larger yield of glucose, but here also maltose was the chief digestion product even though the digestion was continued 40 to 50 times as long as was required for the disappearance of the starch-iodine reaction.

When commercial takadiastase, in quantity sufficient to digest all the starch present in one-half hour to disappearance of the starch-iodine reaction, was allowed to act for 24 hours (at 40° and in the presence of activating salts), the analysis of the resulting digestion mixture and its alcoholic extract indicated that of the total carbohydrate present more than half was maltose, about one-fourth was glucose, and somewhat less than one-fourth was dextrin.

The amylase preparation made from the takadiastase and representing a considerable degree of purification and concentration of both amyloclastic and saccharogenic power, formed in a parallel experiment a somewhat smaller proportion of glucose. This may be due either to the elimination of a maltase in the purification process or to the fact that the purified amylase is less stable than the commercial and therefore would not show as great relative activity in a long as in a short digestion experiment.

**With all three types of amylase** it is noticeable that considerable quantities of dextrin still appear among the digestion products, even when the digestion is allowed to proceed forty to fifty times as long as is required for the disappearance of the starch-iodine reaction.

On the other hand, many of our experiments have shown a larger yield of reducing sugar and smaller yield of dextrin than would correspond with the "resting stage" described by some of the earlier investigators.

The different enzymes all left about 1% of the weight of the "soluble" starch as a very finely divided difficultly filtrable insoluble residue.

There are indications that dextrin, maltose and glucose may not constitute the sole products of the action of amylases upon soluble starch.

### Conclusion.

The experiments lead to the conclusion (1) that any of the amylases

<sup>1</sup> The material here used was Dr. Tanberg's Preparation No. 15 having a diastatic power of 194 ("new scale") which is about 8 times the activity of commercial takadiastase but somewhat less than half the maximum activity thus far attained. See Sherman and Tanberg, *THIS JOURNAL*, 38, 1638.

here studied may form some glucose, (2) that in such conditions as obtain in the usual determinations of diastatic power the yield of maltose so far predominates as to justify the custom of calculating the reducing powers of the digestion products as if due to maltose alone.

#### Detailed Data of the Principal Experiments of the Series of 1914-5.

In the above tables, the data are recorded under abbreviated captions, the significance of which are as follows:

(1) is the weight of dry starch used. (2) is the weight of insoluble matter filtered out. (3) is the percentage of the dry starch consisting of such insoluble matter. (4) is the weight of soluble carbohydrates in the total solution; *i. e.*, total solids less activation salts, less enzyme. (5) is the sum of (2) and (4). (6) is the difference between (5) and (1). (7) is the percentage increase in weight over the weight of dry starch used. (8) is the specific rotatory power for the soluble carbohydrates in the total solution ("T"). (9) is the reducing power expressed in terms of maltose, and (10) in terms of glucose for the whole solution. (11) is the amount of alcohol used for the extraction. (12) is the weight of carbohydrates in the extract solution ("X") and (13) is the weight equivalent to the total solution; *i. e.*,  $(12) \times 1.25$ , since the extraction was made on four-fifths of the original material. (14) is the specific rotatory power for the carbohydrates in the extract solution. (15) and (16) are the reducing power of the extract solution expressed in terms of maltose and glucose, respectively. (17) is the weight of carbohydrate in the residue solution ("R"), *i. e.*, total solids less four-fifths the weight of added activator. (18) is the portion of soluble carbohydrates in the original total solution corresponding to the weight in the residue solution. (19) is the specific rotatory power of the carbohydrates in the residue solution and (20) and (21) their reducing power expressed in terms of maltose and glucose, respectively. (22) is the sum of (13) and (18) and when subtracted from (4) gives the loss of material (23) due to the process.

### EXPERIMENTS UPON STARCH AS SUBSTRATE FOR ENZYME ACTION.

By H. C. SHERMAN AND J. C. BAKER.

Received June 24, 1916.

The forms in which starch has been used as substrate for enzyme action may be grouped as: (1) Natural starch dispersed in water under different conditions of time, temperature, and pressure but without "chemical" treatment; (2) starch which has been subjected to the action of acid (Lintner)<sup>1</sup> or to other chemical treatment (Wolff and Fernbach)<sup>2</sup> to render it "soluble;" (3) fractions of the starch substance which have been separated from the remainder by sedimentation (Tanret),<sup>3</sup> or pre-

cipitation (Maquenne and Roux,<sup>1</sup> Fernbach,<sup>2</sup> Malfitano and Moschkoff,<sup>3</sup> Gruzewska<sup>4</sup>).

In order to ensure uniformity of substrate in successive experiments and to avoid difficulties due to imperfect solution or unequal dispersion on the one hand, or on the other hand the use of substrate representing only a part of the original starch and perhaps contaminated by the reagent or solvent used in its preparation, the consensus of opinion of workers in this field has favored the use of "soluble" starch, prepared by Lintner's method of simply soaking the starch grains in cold hydrochloric acid and subsequently removing the latter by washing with cold water. Such "soluble" starch has been used in nearly all the studies of amylases carried on in this laboratory and has always been found a satisfactory substrate except for certain peculiarities encountered in the case of purified malt amylase.

When soluble starch is acted upon by pancreatic amylase either in purified or commercial form under the conditions used for measuring the amyolytic activities of enzyme preparations, the weight of maltose produced is regularly about half of the weight of starch which disappears. In other words the purified pancreatic amylase having many times the power of commercial preparations shows nevertheless the same relation between amyoclastic and saccharogenic powers.<sup>5</sup> Similarly in experiments upon the amylase of *Aspergillus oryzae*, the amyoclastic and saccharogenic activities were found to increase in about the same proportion as the enzyme was concentrated by purification.<sup>6</sup> But when purified malt amylase preparations were compared with malt extracts no such constancy in the ratio of amyoclastic and saccharogenic powers was found. In this case not only had the purification process altered the ratio of amyoclastic and saccharogenic activities, but evidently also the generally accepted method for measuring amyoclastic action (that of Wohlgemuth) yields misleading results when applied to purified malt amylase.

The present investigation had its origin in an attempt to prepare a substrate sufficiently homogeneous to yield reliable results when used as in the Wohlgemuth method, and developed from this into a study of the differing behavior toward enzymes of the two chief constituents of starch. It was thought that the discrepancy noted in the measurements of amyoclastic action of malt amylase might be due to an unequal susceptibility of the two main constituents of starch<sup>7</sup> to the action of the enzyme, in which

<sup>7</sup> Meyer (Untersuchungen über die Stärkekörner) considered starch to be chiefly

case an approximate separation of the substances might yield a more satisfactory substrate. At the same time it seemed very desirable that the material to be used as substrate in our experiments should not be subjected to treatment with strong reagents nor to solution and reprecipitation, which might involve danger of change in its behavior toward enzymes.

Experiments were, therefore, made to test the feasibility of extracting the more soluble component ("β-amylose," "amylose") while leaving behind the less soluble ("α-amylose," "amylopectin") by carefully regulated treatment of purified potato starch with distilled water. By ultrafiltration or by simple sedimentation we did not obtain satisfactory separations but by use of the centrifuge much better results were obtained.

### **Separation of "Soluble" and "Insoluble" Components of Starch by means of Centrifugal Force.**

When thin starch paste is submitted to centrifugal force it is separated into a lighter, clearer and more limpid layer containing the more soluble constituent (β-amylose of Meyer, amylose of Maquenne and Roux) and a heavier, opalescent, very viscous layer containing the less soluble component (α-amylose of Meyer, amylopectin of Maquenne and Roux, amylophosphate of Tanret). For the purpose of making such separations we have employed three different types of centrifuge, but in all of the experiments here described the Size 1, Type A, 8-tube centrifuge of the International Instrument Company has been used. In these experiments 50 cc. of the starch paste are placed in each of the 8 tubes of the centrifuge and rotated for 30 min. at about 2400 revolutions per min. ("relative force 1024 times gravity"). At the end of such treatment the liquid in each tube is found to have separated into two distinct layers, the heavier opalescent layer usually occupying from one-third to four-fifths of the total volume.

It was thus found possible to carry out a series of experiments, heating the starch with water under different conditions, separating the two portions composed of two substances to which he gave the names α-amylose and β-amylose. Maquenne and Roux (*Loc. cit.*) call about four-fifths of the starch substance "amylose" and about one-fifth "amylopectin." Gruzewska (*Compt. rend.*, 146, 540; 152, 785) by solution in alkali and precipitation with alcohol estimated the "amylopectin" to be 40 to 45% of the starch. Samec (*Koll. Beihefte*, 6, 32) by a modification of Gruzewska's method found 56% of "amylopectin" and only 44% of "amylose," the latter being practically phosphorus-free while the former contained phosphorus as an essential constituent. Tanret (*Bull. soc. chim.*, [4] 17, 83) by successive treatment of starches with hot water, sedimentation and decantation, finds from 70 to 80% of "amylopectin" or "amylophosphate" and 20 to 30% of "amylose." For the material present in larger quantity the term α-amylose not only has priority but is much more appropriate than the term amylopectin. We have, therefore, given preference to Meyer's terminology in this paper, even though some of Meyer's views as to the chemical nature and relationships of the α- and β-amyloses may not be tenable.

tions, observing their properties, and using them as substrates for the study of diastatic hydrolysis.

**Experiments upon Commercial Potato Starch.**—In the earlier of our experiments a good grade of commercial potato starch was used. The starch was handled in air-dry condition and allowance was made for the moisture which it contained when weighing out portions for experiment. All statements of weight or concentration of starch refer, therefore, to the water-free substance. Only one of these earlier experiments will be described here.

In this case starch was gelatinized in 100 times its weight of water at 85°, and the temperature maintained by means of a thermostat while the liquid was stirred continuously. Portions of the liquid were withdrawn and centrifuged at intervals. The centrifugates were studied with reference to volume, viscosity, concentration, and behavior under the action of pancreatic and malt amylases. In the enzyme experiments the time required for the digestion of starch to disappearance of blue iodine reaction, and to disappearance of red reaction with iodine, was observed, and the maltose which had been formed at the time of disappearance of blue iodine reaction was determined. The iodine tests were applied under the conditions prescribed by the Wohlgemuth method and the "disappearance of blue" was considered to be that point at which the color obtained with iodine changed from red-violet (RV) to violet-red (VR), the colors being always determined by comparison with the Milton-Bradley Standard Color Chart as given in Mullikin's *Identification of Pure Organic Compounds*. The data obtained are shown in Table I.

TABLE I.—PROPERTIES OF UNFILTERED CENTRIFUGATES FROM 1% POTATO STARCH PASTES PREPARED AT 85°.

Time of heating.....	1 hour	2 hours	4 hours	6 hours	8 hours
Volume of lower layer.....	60%	66%	65%	61%	47%
Volume of centrifugate.....	40%	34%	35%	39%	53%
Viscosity of centrifugate <sup>1</sup> .....	1.445	1.572	2.130	2.335	3.06
Concentration of starch in centrifugate.....	0.384%	0.444%	0.572%	0.716%	0.816%
Digestion with pancreatin:

To disapp. of red react. (Mins.)	20.0	24.0	32.0	42.0	46.0
Maltose at end of blue in percentage of starch..... (60.5)	48.5	46.2	48.8	44.7	
Digestion with malt amylase:					
To disapp. of blue react. (Mins.)	18.0	19.0	20.0	24.0	26.0
To disapp. of red react. (Mins.)	24.0	28.0	40.0	55.0	65.0
Maltose at end of blue in percentage of starch.....	83.2	81.2	75.0	69.2	68.0

<sup>1</sup> Viscosities are here expressed as time of flow of solution divided by time of flow of water, both at 30°, Ostwald viscosimeters being used.

When starch pastes are separated by centrifugal force as above described, the lower (heavier) layer is found to consist largely of greatly swollen grains. The swelling of the grains increases with duration of heating in water and appears to be due to absorption of water by the "insoluble" constituent of the starch grain, the "soluble" constituent going into solution.

From the data given in Table I for volumes of lower layers and centrifugates from pastes prepared by heating for five different lengths of time at each of three temperatures, it would appear that in this particular series of experiments the swelling of the grains and liberation of the soluble component was the chief effect of heating the starch in 100 times its weight of water up to about 2 hours at 85°, and that the chief result of further heating at 85° was dispersion (or hydration) of the insoluble component into forms (or derivatives) not removable from the centrifugate by the force here employed (about 1000 times gravity for 30 minutes). Microscopic examination showed that the upper layer did contain some swollen grains. In subsequent experiments these were removed by filtering through paper covered with a thin layer of absorbent cotton. Observations upon the iodine reactions and phosphorus content of the two layers obtained in this and several subsequent experiments also bear upon this phase of the problem. The results of the action of amylases upon the centrifugates obtained after different periods of heating in water at 85°, also throw light upon the nature of the starchy material contained in this layer, and upon the differing ratios of amylolytic to saccharogenic powers as between pancreatic and malt amylases. Thus it will be seen from the data given in Table I that the pancreatic amylase acted in much the same way upon the different substrates. The time required for the digestion of the material to a point where iodine no longer gave a blue or violet reaction ("disappearance of blue") was approximately proportional to the amount of starch material present, the time required for "disappearance of red" was approximately twice that for "disappearance of blue" in all cases, and the maltose found at the time when the blue reaction had just disappeared was always about half the weight of the original substrate, as had been found by previous workers in this laboratory in experiments in which the enzyme acted upon soluble starch prepared by the Lintner process. On the other hand, it is apparent that the malt amylase acted differently upon the substrates obtained after different lengths of heating. The time required for disappearance of the red reaction with iodine increased more than did the concentration of the substrate in the successive portions; and the relative yield of maltose at the time of disappearance of the blue reaction is greatest for the substrate first obtained and decreases progressively for the substrates prepared by longer heating.

All of the results are consistent and together they indicate plainly that the continued heating results in dispersion of more and more of the less soluble component of the starch ( $\alpha$ -amylose, amylopectin) into the solution of the more soluble component ( $\beta$ -amylose, amylose).<sup>1</sup>

With pancreatic amylase the digestion of the two components proceeds proportionately, so that the ratio of apparent amylolytic and saccharogenic activity is not materially disturbed by the difference in nature of the substrate; but with malt the two components are hydrolyzed quite differently, so that with increasing proportion of the less soluble component ( $\alpha$ -amylose, amylopectin) in the substrate the ratio of times required for disappearance of the blue and red reactions and the ratio of amylolytic and saccharogenic action are both altered.

**Experiments upon Potato Starch Prepared in the Laboratory.**—For the main series of experiments, starch was prepared in the laboratory from mature August potatoes, with care to prevent contamination by organisms, dust, fumes, or water containing electrolytes. Pastes made by heating this starch in pure water could not be separated by centrifuging as described above. Experiments were then made to test the effect of adding small amounts of known electrolytes to the starch paste before centrifuging, and it was found that the addition of a very small amount of hydrochloric acid or sodium chloride sufficed to ensure a good separation. Since sodium chloride (at least in small amounts) is known to have no injurious effect upon amylolytic enzymes its use was decided upon, and in all subsequent centrifugal separations of 1% starch pastes enough sodium chloride was added to bring the concentration of salt in the final mixture to 0.001 *M*. When 2% starch pastes were to be separated a 0.002 *M* concentration of salt was employed.

The effect of varying the time and temperature of heating was studied in repeated experiments, in all of which the paste resulting from dispersion of the starch was separated by the centrifuge in the manner already described, the centrifugate filtered through filter paper covered with a thin layer of cotton, and the concentration of starch material in the filtered centrifugate was determined by evaporating and drying to constant weight at 80° *in vacuo*. These experiments showed that the bulk of the readily soluble material was extracted from the starch grains very quickly by water at 70 to 80°. When one part of starch suspended in 13 parts of cold water was poured into 87 parts of water heated sufficiently to give the entire mixture the desired temperature and containing sufficient salt to give the desired final concentration, thoroughly stirred for at least one minute until the viscosity no longer seemed to increase, and the paste

<sup>1</sup> There remains the possibility that by heating with water the less soluble component of the starch grain may be slowly changed into the more soluble— $\alpha$ -amylose into  $\beta$ -amylose as suggested by Meyer.

then centrifuged as promptly as practicable (within 10 minutes of the first exposure of the starch to the hot water) the concentration of amylose in the centrifugate was about the same as when the heating was continued for one hour. Prolonged heating (up to 30 hours) caused a very slow gradual increase in the amount of material going into the filtered centrifugate. Thus the concentration after heating at  $80^{\circ}$  for ten minutes to one hour averaged 0.20%; after 19 hours, 0.30%; after 30 hours, 0.35%.

In several cases the lower layer from the centrifugal separation was again treated with hot water and centrifuged a second and a third time, and the material thus extracted was compared as to amount and iodine reaction with the residual material and with the material of the first centrifugate. In this way it was found that the material brought into solution by repeated treatment with hot water, and, therefore, presumably the material which comes slowly into solution on prolonged heating with large excess of water, is different from that contained in the first centrifugate (original upper layer), and apparently consists of a mixture of the  $\beta$ -amylose which constitutes the chief solid of the upper layer and the  $\alpha$ -amylose which is the chief solid of the lower layer or residual gel.

To develop a given *intensity of blue color with iodine* requires from 13 to 18 times as much of the twice washed solids of the residual gel (crude  $\alpha$ -amylose) as is required of the solids of the original centrifugate (crude  $\beta$ -amylose); or, in other words, the solid matter of the  $\beta$ -amylose fraction had 13 to 18 times the blue-forming property<sup>1</sup> of the solids of the  $\alpha$ -amylose fraction, and the solids of the washings (second and third centrifugates) were of intermediate character.

No attempt was made to investigate the exact significance of these differences, which we recognize to depend to a considerable extent upon the amount of iodine arbitrarily chosen by Wohlgemuth for making such tests, because for the purposes of this investigation it was desired that the material going into the substrate should be as nearly homogeneous and as little changed from the form in which it exists in the natural starch as is possible. For these reasons it was decided to use in the separation of  $\beta$ -amylose only a short exposure of the starch to hot water as described above, centrifuging within 10 minutes and determining the solids in the centrifugate after filtering as already explained. Experiments at different temperatures indicated that the best results were obtained in heating at  $75^{\circ}$  in the preparation of 2%, or  $80^{\circ}$  in the preparation of 1% pastes.

*The viscosities as influenced by heating and by treatment with acid or alkali* also furnish evidence of a pronounced difference between the

<sup>1</sup> It is hardly necessary to say that in speaking of this as a property which helps to differentiate the two fractions, we do not mean to convey the impression of a definite chemical reaction in either case.

substances contained in the two layers separated by the centrifuge, the " $\beta$ -amylose" of our fractionation resembling the "amylose" of Gruzewska and of Samec in this respect and differing greatly from the  $\alpha$ -amylose fraction ("amylopectin").

Thus in an experiment in which the filtered  $\beta$ -amylose layer as obtained had a concentration of 0.4% and a viscosity of 1.13 the  $\alpha$ -amylose layer when diluted to the same concentration showed a viscosity of 1.18. On heating the  $\beta$ -amylose solution its viscosity was lowered to 1.03 after 5 minutes' and 1.02 after 20 minutes' boiling. Boiling the  $\alpha$ -amylose solution of the same concentration for 5 minutes raised its viscosity to 1.38, and heating for 1 hour in the autoclave at 125° increased it to 1.81; further heating in the autoclave caused decrease of viscosity—to 1.13 at the end of 2 hours' and 1.12 at the end of 3½ hours' heating at the same temperature.<sup>1</sup>

The addition of sufficient hydrochloric acid to give a concentration of 0.02 *N* did not change the viscosity of a  $\beta$ -amylose solution, and sodium hydroxide in equivalent concentration increased the viscosity only slightly. This is in accordance with the results of Samec<sup>2</sup> who finds that the viscosity of a starch solution (chiefly  $\alpha$ -amylose) is decreased by hydrochloric acid and increased by sodium hydroxide to a very marked extent while the viscosity of a solution of "amylose" ( $\beta$ -amylose) prepared by his modification of Gruzewska's method was not appreciably affected.

The two fractions into which starch is divided by the process above described and which, although not quantitatively free from each other, are for convenience referred to simply as  $\alpha$ - and  $\beta$ -amylose, also differ from each other in their behavior as regards *retrogradation*. We have had no evidence of retrogradation in any of our  $\alpha$ -amylose solutions, while the  $\beta$ -amylose solutions show the phenomenon to a pronounced degree, the more so the lower the temperature or the higher the concentration.

In an experiment to test this property  $\beta$ -amylose solutions of 0.6 and of 0.2% were allowed to stand in the refrigerator for three weeks and were then filtered. The filtrates contained only 0.04 and 0.037%, respectively. The completeness of this retrogradation is a further indication of the identity of this material with Gruzewska's amylose.<sup>3</sup> It seems not improbable that in ordinary starch pastes the  $\alpha$ -amylose may act as a protective colloid to the  $\beta$ -amylose. In all of the cases observed by us the retrogradation of the  $\beta$ -amylose has occurred more readily in the absence than in the presence of amylase, the enzymes being employed in purified form and low concentration. The suggestion that the amylase may exert a

<sup>1</sup> For discussion of effect of heat treatment upon viscosities of starch solutions see Harrison, *J. Soc. Dyers and Colorists*, April, 1911.

<sup>2</sup> Samec, *Koll. Beihefte*, 4, 132; 6, 32.

<sup>3</sup> *Compt. rend.*, 152, 785 (1911).

coagulating influence upon the substrate seems superfluous, at least as regards enzymes of the degree of purity used in these experiments. The phenomena observed by Maquenne and Roux and attributed by them to an amylocoagulase may possibly have been due to the digestion of  $\alpha$ -amylose and consequent removal of its protective effect upon the  $\beta$ -amylose.

In order to avoid retrogradation in our digestion experiments the solutions were autoclaved, allowed to cool to  $40^{\circ}$  and then promptly mixed with the enzyme solution, the activating salts being added at the same time (not mixed with the substrate in advance). Omission of such precautions is likely to result in cloudy digestion mixtures and delayed iodine end points.

The phosphorus content of the two fractions separated by the centrifuge was studied as a further indication of the relative amounts of  $\alpha$ - and  $\beta$ -amyloses and the extent to which they are differentiated by the procedure here used.

According to Samec, the phosphorus of starch is all contained in the  $\alpha$ -amylose ("amylopectin") portion. If, then, the centrifuge separates the  $\alpha$ - and  $\beta$ -amylose, the phosphorus should be found in the lower layer; but since in Northrop and Nelson's experiments<sup>1</sup> about one-tenth of the phosphorus escaped recovery it is possible that the  $\alpha$ - and  $\beta$ -amyloses might be separated by the centrifuge and still a fraction up to 10% of the original phosphorus might be found in the upper layer or diffused throughout the dispersion medium. In several experiments in which we have determined the phosphorus, the centrifugates (upper layers) constituting about 70% of the total volume have never contained more than about 2% of the total found. Our results are thus in harmony with the findings of Northrop and Nelson and with the view that  $\alpha$ - and  $\beta$ -amylose ("amylopectin" and "amylose") are separable by heating with water and centrifuging as here described.

The amounts of phosphorus found in the  $\beta$ -amylose fraction are but little, if any, above the limits of experimental error, and for most purposes might be regarded as negligible, but since the concentration of solids in this layer is only about 0.20% the percentage of phosphorus in the solids is about one-tenth as high for this fraction as for the whole starch, so that it seemed desirable to ascertain if possible whether the phosphorus of the  $\beta$ -amylose layer were present merely as diffusible phosphate or in the form of  $\alpha$ -amylose or other non-diffusible material.

The centrifugates ( $\beta$ -amylose layers) from several experiments were saved and united, a portion of the solution reserved and the remainder dialyzed in a collodion bag against 5 to 8 times its volume of redistilled water for 8 days, the water being changed every day. A portion of the

<sup>1</sup> THIS JOURNAL, 38, 472 (1916).

centrifuge residue ( $\alpha$ -amylose layer) was diluted to a similar concentration and dialyzed under the same conditions. With the kind assistance of Dr. I. Greenwald of the Harriman Research Laboratory, the phosphorus content of these solutions was determined nephelometrically by precipitating as strychnine phosphomolybdate according to the method of Pouget and Chouchak.<sup>1</sup> The  $\beta$ -amylose layer showed before dialysis 0.00002% and after dialysis 0.00001% of phosphorus; the  $\alpha$ -amylose layer after dilution to corresponding concentration of solids showed 0.00195% before, and 0.00180% after dialysis. Thus the eight-day dialysis had removed half of the phosphorus of the  $\beta$ -amylose layer and somewhat less than one-tenth of that of the  $\alpha$ -amylose layer. Calculating the phosphorus in percentage of the starch solids present it is found before dialysis to constitute 0.068% of the  $\alpha$ -amylose fraction and 0.010% of the  $\beta$ -amylose fraction, or about one-seventh as much in the latter case as in the former. If the phosphorus were assumed to be present only in the form of  $\alpha$ -amylose it would follow that the amylose of the upper layer from the centrifuge is about one-seventh  $\alpha$ -amylose and six-sevenths  $\beta$ -amylose; but since at least half of the phosphorus of this fraction is dialyzable it appears probable that well over nine-tenths of the starch material in the upper layer from the centrifuge tube is  $\beta$ -amylose (using this term to designate the phosphorus-free fraction of starch which gives a pure blue reaction with iodine). From the comparison of iodine color reactions and solubilities it also appears probable that the starchy material of the lower layer after separation and two washings in the centrifuge is at least nine-tenths  $\alpha$ -amylose.

Thus it appears that by the method of regulated dispersion and centrifugal separation here described it is feasible to divide potato starch into two fractions, one of which is more than nine-tenths  $\alpha$ -amylose and the other more than nine-tenths  $\beta$ -amylose. If amylases behave differently toward  $\alpha$ - and  $\beta$ -amylose it should be possible to study their differences in behavior by experiments in which these two fractions are used side by side as substrates for the action of the enzyme. The data recorded below are typical of those which we have obtained in several series of comparative experiments of this sort.

#### Experiments with Enzymes.

In the experiments with enzymes recorded in this paper we have used each enzyme in the presence of its optimum concentration of salt and phosphate as determined in previous work in this laboratory.

Except as different enzymes with their appropriate activators were used, the only variable factor was the nature of the substrate. All digestions were conducted at 40° with all the precautions as to purity of reagents and water used, and accurate control of time and temperature,

<sup>1</sup> *Bull. soc. chim.*, [4] 5, 104 (1909); 9, 649 (1911).

which have been described in previous papers.<sup>1</sup> The enzyme hydrolysis of four potato starch substrates— $\alpha$ - and  $\beta$ -amyloses, Lintner soluble starch, and whole starch autoclaved—has been studied at two concentrations of substrate, 0.16% and 0.5%. For the sake of brevity only the latter will be described.

**Preparation of Substrates.**—The  $\alpha$ -amylose substrate was prepared by centrifuging a 1% starch paste made at 85° in a concentration of 0.001 *M* sodium chloride as previously described. The supernatant  $\beta$ -amylose layer was decanted off and an equal volume of hot 0.001 *M* sodium chloride stirred into the  $\alpha$ -amylose layer and this again centrifuged. This washing was repeated and the residue then diluted to the original volume and this solution (about 0.8%) heated in autoclave at 125° for 2½ hours. The exact concentration was then determined by evaporating a portion *in vacuo* at 80°. When about to start an experiment, this solution was sufficiently diluted with water so that when mixed with the activator and enzyme solutions the desired final concentration of 0.5% substrate would be obtained.

The  $\beta$ -amylose substrate was prepared by centrifuging a 2% starch paste prepared at 75° containing sodium chloride in 0.002 *M* concentration. The supernatant liquid from the centrifuge tube was filtered through paper covered with a thin layer of absorbent cotton. About 170 cc. of 0.4% filtered  $\beta$ -amylose solution were obtained from 400 cc. of 2% starch paste. Two such filtrates were usually united. A portion of this solution was evaporated *in vacuo* at 80° to determine the exact concentration of  $\beta$ -amylose and a larger measured volume (sufficient for the experiment contemplated) was concentrated by evaporation to about 0.8%, autoclaved in the same manner as the  $\alpha$ -amylose solution and finally brought exactly to the desired concentration.

"Autoclaved starch" was prepared by heating an 0.8% starch paste in the autoclave as described under  $\alpha$ -amylose, and then bringing to the proper concentration.

"Soluble starch" (Lintner) was "dissolved" by boiling with water for 10 minutes and was not heated in the autoclave.

The initial reducing power of each substrate was determined and this value subtracted from that found in the digestion experiments.

Each digestion experiment was started by measuring the enzyme solution into a flask and pouring into it the proper volumes of substrate solution and of the solution of activating salts so that the concentration of substrate in the final digestion mixture was exactly 0.5%. The substrate and activator solutions were measured at 40° and this temperature was maintained throughout the experiment, portions being withdrawn by

<sup>1</sup> THIS JOURNAL, 32, 1073, 1087; 33, 1195; 35, 1617; 37, 623.

pipet from time to time without removing the main solution from the thermostat.

The four experiments of a set were started at intervals of one minute so that portions of each might be withdrawn in succession after exactly equal digestion periods. Each measured portion as withdrawn was at once delivered into a flask containing mixed Fehling solution, and the reducing sugars determined at once, following the procedure described by Sherman, Kendall and Clark<sup>1</sup> and calculating the result as maltose by means of Defren's table.<sup>2</sup> In order to simplify the tabular statement and comparison of the results, the weights of reduced copper and the corresponding weights of maltose are omitted and only the maltose as calculated in terms of the amount theoretically obtainable from the substrate and the corresponding velocity constant are printed. Since it has been shown<sup>3</sup> that even purified amylases may form appreciable amounts of glucose as well as maltose, it is possible that the figure for maltose calculated from the reduction of Fehling solution may, in prolonged digestions or under special conditions of enzyme or substrate, exceed the theoretical yield.

**Action of Pancreatic Amylase.**—The four substrates above described were quantitatively compared as regards their digestion by pancreatic amylase, first in the form of a high grade commercial pancreatin (Pancreatin 6) and then in the form of a highly purified laboratory preparation (Preparation 59). The results are shown in Tables II and III, respectively.

It will be seen that under the action of pancreatic amylase, whether in commercial or purified form, the yield of reducing sugar is higher for the  $\beta$ -amylose than for the  $\alpha$ -amylose fraction at each of the stages at which the digestion mixture was tested, the difference becoming greater as the digestion proceeds. The amount of enzyme here used was small in order that the progress of the reaction might be slow enough to be followed experimentally through the earlier stages. Under these conditions, at the end of 24 hours, when the last of the digestion mixture was withdrawn for testing, the reaction was still in progress and the yield of maltose had reached in the two series of experiments, respectively, only 56.9 and 55.1% of theoretical in the  $\alpha$ -amylose, and 77.5 and 84.5% in the  $\beta$ -amylose fraction.

Since each of the successive reactions by which maltose is formed is an hydrolysis taking place in water solution, and, therefore, essentially a unimolecular reaction, and it is the catalytic effect of the enzyme which causes these reactions to proceed at a measurable rate, it follows that the speed of formation of maltose may be expressed in terms of  $k$  of the unimolecular reaction formula ( $1/t \log a/a - x = k$ ) and that (under a given set of conditions as in either one of the two sets of experiments here described) the magnitude of  $k$  at any given stage in the experiment may be regarded as an indication of the efficiency with which the formation of maltose is catalyzed at that stage. Constancy of  $k$  from the beginning of the experiment until a practically theoretical yield of maltose is obtained would indicate that the group of hydrolyses which produce maltose (that of starch and of each of the resultant dextrins) is equally catalyzed by the enzyme throughout; whereas if the digestion yields at any stage a dextrin which is less readily hydrolyzed by the enzyme, the value of  $k$  must diminish. A fall in the value of  $k$  may, therefore, serve as an indication of the formation of a "resistant dextrin." When equal amounts of the same enzyme act on equal amounts of different sub-

strates under identical conditions, a comparison of the values for  $k$  may indicate an earlier or a larger production of "resistant dextrin" from one substrate than from the other.

The data in Table II show in all cases a decided diminution of the velocity of reaction (expressed as value of  $k$ ) between the 6th and the 18th hour. Comparing the yields of maltose from the different substrates at these periods it is plain that the decrease in value of  $k$  began at a lower yield of maltose in the  $\alpha$ -amylase than in the  $\beta$ -amylase fraction, indicating that the former yields more of the relatively resistant dextrin than the latter, or that its dextrin is more resistant than the corresponding dextrin from  $\beta$ -amylase. Lintner soluble starch and autoclaved whole starch gives intermediate results, but approach the behavior of  $\alpha$ -amylase more closely than that of  $\beta$ -amylase as is consistent with the other evidence that they consist much more largely of the former than of the latter.

Similar comparison of the data obtained in experiments with other amylases described below will show that the stage of digestion at which the value of  $k$  begins to diminish depends upon the enzyme as well as the substrate but that in all cases the indications of "resistant dextrin" are much more pronounced in the  $\alpha$ -amylase than in the  $\beta$ -amylase fraction.

There are, of course, many causes which may contribute to the slowing of the reaction as the hydrolysis proceeds, such as the destructive action of water upon the enzyme, inactivation of enzyme by combination with hydrolytic products, etc. Without entering into discussion of such factors here, it may be pointed out that the arrangement of these experiments was such that any distinctly different behaviors of  $k$  in experiments recorded in any one table (such as discussed in the above paragraph referring to Table II) may be interpreted as due to some difference in the substrate or its hydrolytic products. The general relations noted from the data of Table II will be seen to hold true for those of Table III also.

**Action of Malt Amylase.**—Parallel tests upon the  $\alpha$ - and  $\beta$ -amylase substrates at 0.5% concentration were made with a freshly prepared malt amylase preparation of a diastatic power of 957<sup>1</sup> prepared essentially as described in previous papers from this laboratory, but precipitated at a concentration of alcohol slightly higher than usual, *viz.*, 65–70%; and also with a preparation purified in the usual way and in which the final active precipitate was obtained at a somewhat lower concentration of alcohol, *i. e.*, Preparation 151, precipitated at 57.5 to 65% alcohol, diastatic power 1240.<sup>1</sup> Except for the kind and amount of enzyme used, the experiments were in all respects similar to those with pancreatic amylase just described. The results with these two malt amylase preparations are given in Tables IV and V, respectively.

Comparison of the data of Tables IV and V shows that the purified malt amylase preparations exert in the earlier stages of the digestions a greater saccharifying action upon the  $\alpha$ -amylose than upon the  $\beta$ -amylose substrate, while in the later stages the  $\beta$ -amylose shows the greater yield of maltose.

The notable feature of the action of malt amylase upon the  $\beta$ -amylose substrate is the striking way in which the speed of formation of maltose is maintained as compared either with the action of this enzyme upon other substrates or the action of other amylases upon this substrate. In the experiment with a small amount of enzyme (Table IV) the values of  $k$  show no decrease until the formation of maltose is nearly complete, and with a larger amount of enzyme (Table V) the values of  $k$  increase, the time curve being substantially linear, up to a nearly theoretical yield of maltose. This may be expressed as a maintenance throughout the process of the linear relationship usually noted in the earlier stages of such

hydrolytic enzyme actions. The explanation is probably to be found in accumulation of hydrolyzable products and the efficiency with which the enzyme catalyzes the later of the series of consecutive hydrolyses by which maltose is produced. Simultaneous effective catalysis of the successive steps in the process would naturally tend to increase the value of  $k$  as computed from the simple unimolecular reaction formula and this tendency will be further augmented by the fact that the velocity of the reaction during the later stages is compared with that shown at the beginning of the process where in the case of this enzyme the  $\beta$ -amylose is hydrolyzed less readily than are the other substrates. With the small amount of enzyme used in the experiments of Table IV this tendency toward a rise in the value of  $k$  suffices merely to balance the factors which tend toward a loss or inactivation of the enzyme; whereas with the larger concentration of enzyme in the experiments of Table V the latter factors are not appreciable and the rise in value of  $k$  becomes very pronounced. Thus the detailed study of the course of the hydrolysis under the influence of a precipitated malt amylase of this character brings out a new difference in behavior between the  $\alpha$ - and  $\beta$ -fractions of the starch.

In all cases the saccharification of the substrate had proceeded to a much higher yield of maltose from  $\beta$ -amylose than from  $\alpha$ -amylose when the concentration of enzyme was such as would be used in determinations of diastatic power and the experiments were sufficiently prolonged to produce maltose up to or beyond half the theoretical yield.

When the amount of enzyme used is much larger the same result may be obtained in a short time as shown in Table VI.

TABLE VI.—HYDROLYSIS OF  $\alpha$ - AND  $\beta$ -SUBSTRATES WITH A RELATIVELY LARGE AMOUNT OF PURIFIED MALT AMYLASE (PREPARATION 153).

154 min.....	71.4	100.8

Evidently even a relatively large amount of enzyme does not readily hydrolyze the material which remains in the  $\alpha$ -amylose fraction after two-thirds of the theoretical amount of maltose has been produced, while in the  $\beta$ -amylose fraction under the influence of the same amount of enzyme the hydrolysis runs rapidly to a theoretical yield of maltose. It thus appears that the "resistant dextrin" emphasized by many previous investigators as a product of the action of malt amylase upon starch is derived only from the  $\alpha$ -amylose and not from the  $\beta$ -amylose fraction. After the theoretical yield of maltose from  $\beta$ -amylose has been obtained, the increase in reducing power is exceedingly slow, indicating that even

this amount of purified malt amylase has only a slight hydrolytic action upon maltose.

The rapid digestion of  $\beta$ -amylose in this experiment explains the statement of Maquenne and Roux<sup>1</sup> to the effect that "amylose" ( $\beta$ -amylose) is immediately hydrolyzed to the theoretical amount of maltose by malt, since in their experiments very liberal amounts of malt extract were used.

**Action of the Amylase of *Aspergillus Oryzae*.**—Experiments upon Lintner soluble starch, autoclaved whole starch, and  $\alpha$ - and  $\beta$ -amylose substrates all at 0.5% concentration have been carried out as described above with the amylase of *Aspergillus oryzae* prepared in this laboratory by Dr. A. P. Tanberg from takadiastase by the purification method described elsewhere.<sup>2</sup> The preparation here used was No. 22b having a diastatic power of 502 as expressed on the scale in use in this laboratory. This corresponds to a Lintner value of about 750. The Wohlgemuth value of this preparation was about 1,000,000.

The results obtained with this amylase preparation are shown in Table VII.

From the data given in Table VII together with the results of two other series not reproduced here, it may be concluded that the purified amylase of *Aspergillus oryzae* exerts essentially the same saccharogenic action upon Lintner soluble starch, autoclaved whole starch and the  $\alpha$ -amylose substrate, while upon the  $\beta$ -amylose substrate it shows a greater saccharogenic action at whatever stage in the digestion the results be compared. The speed of hydrolysis was not so well sustained in this case as with the other amylases; even in the case of the  $\beta$ -amylose substrate there is here a falling off of the rate of saccharogenic action before the reducing

<sup>1</sup> *Compt. rend.*, 140, 1303 (1905).

<sup>2</sup> Sherman and Tanberg, *THIS JOURNAL*, 38, 1638 (1916).

sugar reaches the equivalent of 70% of a theoretical yield of maltose, notwithstanding the fact that this amylase is more active in hydrolyzing maltose to glucose than is either pancreatic or malt amylase. This property is doubtless related to the high ratio of amyloclastic to saccharogenic activity of this enzyme which will be considered in the next section.

**Relation of Amyloclastic to Saccharogenic Action.**—In many of the experiments comparing the different substrates the time of disappearance of the blue or violet reaction with iodine was noted and the amount of maltose which had been formed at this time was found either by direct determination or by interpolation from the determinations of reducing power made at known intervals in the course of the same experiment. While no great accuracy is to be expected of such attempts to determine the stage of digestion at which the starch disappears, as judged by the iodine test, yet they permit comparisons of the amyloclastic and saccharogenic activities which at least are not open to such gross discrepancies as may arise when comparisons are made between saccharogenic powers as ordinarily determined and amyloclastic powers determined by the Wohlge-muth method.<sup>1</sup>

In the case of pancreatic amylase the present experiments show with each of the four substrates a maltose production from 35 to 50% of the theoretical at the point of disappearance of the blue or violet color reaction with iodine. Allowing for the difference in experimental conditions this may be considered as a confirmation for all four substrates of the ratio of about 2 : 1 previously established for the action of pancreatic amylase upon Lintner soluble starch.

In the experiments with the amylase of *Aspergillus oryzae* the iodine end point occurred at a much earlier stage in the saccharogenic action, usually when from 20 to 30% of the theoretical yield of maltose had been produced. This high ratio of amyloclastic to saccharogenic activity and the relatively early decrease in velocity of maltose formation noted above are both indications that this amylase exerts a more pronounced catalytic effect upon the earlier than upon the later of the hydrolyses involved in the transformation of starch through dextrins into maltose.

Malt amylase, on the other hand, is, as shown by the data of Tables IV and V, an active catalyst of sugar production even in the relatively advanced stages of the process; and apparently it does not correspondingly catalyze the complete disruption of the material to which the iodine test is due since the iodine end point is found only at a much more advanced stage of sugar production with this than with either of the other amylases. When acting upon Lintner soluble starch, autoclaved whole starch, or the  $\alpha$ -amylose substrate the malt amylase preparations caused disap-

<sup>1</sup> For a discussion of these discrepancies see Sherman and Schlesinger, *This JOURNAL*, 35, 1784-90.

pearance of the iodine test only when from 65 to 80% of the theoretical yield of maltose had been produced; and when acting upon the  $\beta$ -amylose substrate, only when the maltose production had reached 85 to 95%. Thus the "delayed iodine end point" remarked in previous papers as characteristic of the hydrolyses induced by purified malt amylase, is found to be a noteworthy feature of its action upon both  $\alpha$ - and  $\beta$ -amylose.

### Summary.

Dispersions of commercial potato starch in water or of purified potato starch in water containing a small amount of electrolyte (sodium chloride) have been separated by centrifugal force into a heavier, very viscous, opalescent layer containing the more abundant, less soluble component of the starch (Meyer's  $\alpha$ -amylose, Maquenne's amylopectin), and a lighter, limpid solution containing the less abundant, more soluble component (Meyer's  $\beta$ -amylose, Maquenne's amylose).

In designating these two chief components (or derivatives) of starch the terminology of Meyer is preferred to that of Maquenne, not only on grounds of priority but also as being much more appropriate in view of our present knowledge of the relative abundance of the two components, their properties as compared with the typical properties of starch, and their behavior toward the amylases.

The centrifugal method here described does not completely separate either component from the other but affords a means of approximate separation in which the danger of contamination, denaturization, or retrogradation is minimized and which is well adapted to the study of the effects of the different amylases.

Pancreatic amylase both in commercial and in highly purified form produced reducing sugar more rapidly from  $\beta$ -amylose than from  $\alpha$ -amylose, autoclaved starch, or Lintner soluble starch, the last three giving very similar results when used as substrate for this enzyme. Not only does the  $\beta$ -amylose substrate show larger yield of maltose at each of the various time intervals tested, but the initial speed of hydrolysis is better maintained with this substrate than with either of the others.

Purified malt amylase shows in the earlier stages of its action a somewhat greater yield of maltose from  $\alpha$ - than from  $\beta$ -amylose. As the digestion proceeds, the saccharogenic action of this enzyme upon  $\alpha$ -amylose becomes slower while its action upon  $\beta$ -amylose is well sustained so that in cases in which the hydrolysis proceeds to the production of more than half the theoretical yield of maltose, the final result shows a greater saccharogenic action upon  $\beta$ - than upon  $\alpha$ -amylose. The results obtained upon autoclaved starch and Lintner soluble starch are very similar to those found with  $\alpha$ -amylose.

The amylase of *Aspergillus oryzae* digests Lintner soluble starch, autoclaved whole starch and  $\alpha$ -amylose at about equal rates, and  $\beta$ -amylose

at a somewhat higher rate. Its action upon the  $\beta$ -amylose substrate is, however, not so well sustained as that of pancreatic or malt amylase. This relatively early falling off in the speed of sugar formation together with the high ratio of amylolytic to saccharogenic power indicate that this amylase is a more active catalyst of the earlier than of the later stages of the hydrolysis.

Contrasting the action of comparable amounts of the three different amylases it appears that they catalyze the successive stages of the hydrolysis of  $\beta$ -amylose and its products at relatively different velocities. The time curve for pancreatic amylase is practically logarithmic up to the production of about three-fourths the theoretical amount of maltose while beyond this point the reaction proceeds at a lower velocity. Compared with this result, the catalytic effect of the amylase of *Aspergillus oryzae* is more pronounced in the earlier and less pronounced in the later stages, while purified malt amylase is relatively less efficient in the earlier stages but catalyzes the later stages more efficiently.

In the digestion of  $\alpha$ -amylose all of the amylases showed more pronounced catalytic effect upon the earlier than upon the later stages of the digestion. Starch pastes made at low temperatures ( $65-80^{\circ}$ ), autoclaved starch, and Lintner soluble starch all resemble the  $\alpha$ -amylose rather than the  $\beta$ -amylose substrate in their behavior toward all three amylases, doubtless because  $\alpha$ -amylose is the chief component of all these forms of starch.

The separation of starch into its  $\alpha$ - and  $\beta$ -fractions made possible a more satisfactory study of the course of the amylase hydrolyses because of the greater homogeneity of the new substrates. All the data pertaining to the earlier stages of these hydrolyses indicate that Lintner soluble starch is well adapted to its purpose as substrate for testing the activities of the different amylases and that its use leads to conservative estimates of the diastatic powers of purified preparations.

Tested upon any of the four substrates here studied, the three amylases show distinctly different ratios of amylolytic to saccharogenic powers.

### CORRECTIONS.

Page 1366, line 7 from bottom: after the words "to  $170^{\circ}$ " insert "with aniline."

In the article by C. E. Hudson in the August number of THIS JOURNAL (p. 1572, line 22) the specific rotation of trehalose octacetate in chloroform should be " $+162^{\circ}$ " instead of " $-162^{\circ}$ ."

On page 1569, line 11 from the bottom, "melibiose" should be "gentiobiose."

## NEW BOOKS.

**Practical Physical Chemistry.** By FRANCIS W. GRAY. Lecturer in Charge of the Physical Chemistry Department, Aberdeen University. XVI and 211 pp. 61 figs. Macmillan and Co. New York. Price, \$1.25.

This is an excellent little manual for a first course in laboratory work in physical chemistry. The thirty-nine "exercises" include all the methods ordinarily given in such a course. They are arranged in chapters or groups, each group being preceded by a brief, clear statement of the fundamental principles involved in the experiments which follow. The laboratory directions are precise, adequate, and accompanied by well executed and intelligible diagrams. The author lays stress on the fact that he has so planned that no one exercise requires more than the usual period of two or three hours for its completion, and this is a good feature. The first thirty-five pages are devoted to a valuable discussion of "Accuracy" and "Errors;" the last seventeen to "Tables" and "Useful Data."

The style is uniformly concise and lucid, producing a most favorable impression on the reader, but occasionally one feels that this brevity is carried a trifle too far, and that a little more explanation in the text would be desirable. It would forestall a good many questions which will inevitably arise in the minds of those new to the work. The only thing which disturbed the enjoyment of the reviewer in reading this book was the appearance, four or five times, of the unfamiliar word "dissolecule," meaning molecular weight. Additions to the already unnecessarily long list of "special" words should be made only when it is unavoidable. But one small blemish can readily be forgiven among so much that is admirable.

S. LAWRENCE BIGELOW.

**A Laboratory Course in Organic and Physiological Chemistry.** By A. P. LOTHROP, PH.D., Assistant Professor of Physiological Chemistry, Queens University. R. Uglow & Co., Kingston, Ontario. 1915. 83 pp.

The rapid development of physiological chemistry in the past few years is indicated among other things by the large number of laboratory manuals which are appearing. This indicates that the science is still in a state of flux, that the teaching has not yet been standardized, or at any rate that there is as yet no generally accepted opinion as to what should be covered in the course and how it should be taught. Each teacher makes his own laboratory course. Of the several such manuals which have appeared in the past year, this is one of the simpler and older fashioned. It contains some simple experiments in organic chemistry and following these the ordinary, simpler tests for special substances and methods of examination of certain tissues and the urine. The experiments are clearly described, the directions are printed on one side of the page only leaving space for the recording of the results in the book itself, and the student is generally not told what to observe but only to write down

what he sees. There is no explanation of any of the reactions or observed facts, the author evidently expecting that this will be supplied by the text-book or brought out in recitation. Only one or two quantitative methods are given for the examination of the urine.

The reviewer is of the opinion that for modern, first-class medical schools, in which organic chemistry is required for entrance, the organic chemistry experiments are superfluous. If these were left out, the book could be much improved, without lengthening it, by the introduction of some of the modern quantitative chemical methods for the examination of blood and the secretions of the body. The book represents about what was required in most medical schools ten to fifteen years ago.

THE OSMOTIC PRESSURE OF SUCROSE SOLUTIONS AT 30°.<sup>1</sup>

By J. C. W. FRAZER AND R. T. MYRICK.

Received June 17, 1916.

Introduction.

The purpose of this work was to modify the method of measuring osmotic pressures developed by Morse and Frazer; so that it would be applicable to a study of concentrated solutions and, possibly, to solutions of electrolytes. This demands two things: first, the semipermeable membrane must have greater strength in order to withstand the greater pressures and, second, it must be able to establish equilibrium between the "escaping tendencies" of the solvent on the two sides of the membrane much more quickly, so that a measurement may be secured before the ions of electrolytes have time to destroy the colloidal nature of the membrane. Greater strength and greater speed of action have both been secured and the efficiency of the method for the measurement of the osmotic pressure of concentrated solutions, tested and proven. Its applicability to electrolytes is an unsettled question, but the prospects are every encouraging. It is planned to make a thorough trial of this in the near future.

The method<sup>2</sup> of measuring osmotic pressure developed in this laboratory is in brief as follows: A semipermeable membrane of copper ferro-

<sup>1</sup> This work has been aided by the Carnegie Institution of Washington, D. C.

<sup>2</sup> *Pub. Carnegie Inst.*, No. 198.

cyanide is electrolytically deposited on the inside and in the pores, near the inner surface of a clay cell. The solution to be measured is placed inside of this cell and a manometer is tightly fastened in its mouth. The cell is then immersed in the solvent and the pressure, developed by the passage of solvent through the membrane into the solution, is registered on the manometer.

The modification of this method, which it is the purpose of this article to describe, is essentially a reversal of the above-mentioned process. The membrane is deposited on, and in the pores near, the outer surface of the cell. The cell is fastened inside of a hollow bronze cylinder to which the manometer is attached. The solution to be measured is placed inside of the cylinder around the clay cell, the solvent being placed inside of the latter. This position of the membrane is similar to that used by Berkeley and Hartley.<sup>1</sup> However, these investigators applied mechanical pressure to the solution until equilibrium was established, while in the present instance the solution developed its own pressure as in the apparatus used heretofore in this laboratory.

#### Description of the Apparatus.

The details of construction are shown in the accompanying diagram (Fig. 1) in actual size. M is the clay cell with the membrane of copper ferrocyanide K deposited on its exterior. This extends only as far, as indicated by the heavy line K, the neck and shoulder of the cell being glazed to ensure tight joints. J is the bronze cylinder into which the cell is fastened by means of the plug P. The latter has three legs upon which the apparatus stands and which serve as a means of screwing the plug into the cylinder. N is a thick rubber washer and O is a piece of commercial "Rainbow Packing," about a millimeter and a half thick. This packing gives perfect satisfaction, while ordinary rubber will not withstand higher pressures. At all other joints, N, G, H, the packing is surrounded on all sides so it can not get away, hence in these places the softer rubber washers answer very well. In fact, it is desirable to have N and G thick (about 4 mm.) and soft so that initial pressure may be secured by their compression.

R is a glass U-tube held in the mouth of the cell by means of the rubber stopper Q. This is simply to keep the solvent L up in the cell and yet leave it open to the atmosphere. I is the solution to be measured. E is the manometer attachment and is fastened onto the cylinder by means of nut F, G being a thick rubber washer described above. A is a piece of capillary glass tubing to which the manometer is sealed. The square shoulder at the lower end of A is secured by sealing on to a piece of tubing, of the size desired for A, another piece, having somewhat larger external dimensions. The joint is kept soft and the glass allowed to flow together

<sup>1</sup> *Trans. Roy. Soc., (A)* 206, 481 (1906).

until a considerable enlargement is secured, the internal diameter being kept of original size by careful blowing. After cooling, the larger piece of tubing is cut off close to the enlarged joint. A is then mounted in the lathe and the enlarged end ground to the desired size and shape. The grinding is done with carborundum dental wheels mounted on the lathe carriage and rotated at a high speed by a small electric motor. In this manner the lower end of A is made to fit accurately into the lower end of E, as shown in the diagram. To hold A in position, B is sealed onto A by means of sealing wax (Khotinsky) and after putting D into position, C is screwed onto B. Now it will be seen that by turning D to the left, A is raised and held tightly in position in E against the washer H. By turning D to the right, A is lowered and excess solution is allowed to escape. This method of joining glass and metal is of general application and has proven most satisfactory. Such a joint will hold tight under any pressure which will not actually break the glass.

Several points of advantage over the old type of cell deserve especial mention. In the first place the clay cell will withstand far greater pressure exerted upon its exterior than upon its interior, as would be expected from a consideration of the principles of arch construction. Secondly, the membrane itself is made stronger, for the pressure tends to force it farther into the pores and so compresses it, making it more firm and compact. With the membrane on the inside of the cell the pressure of the inclosed solution tends to expand the membrane out into the pores of the cell thus stretching the particles of the membrane and so making ruptures more likely to occur.

The new cells are about the same size as the old, but having the membrane on the outer surface greatly increases its area, hence equilibrium is much more readily established.

Fig. 1.

A distinct advantage in construction is apparent in the method of attaching the manometer. In the case of the old apparatus the lower end of the manometer terminated in a rubber-covered, cone-shaped attachment which was forced into the tapered neck of the cell. This often resulted in splitting the cell simply by the mechanical pressure used in securing a tight joint between manometer and cell. In the apparatus described above it will be noticed that the manometer is attached, not to the *cell*, but to the bronze cup, hence a tight joint is easily secured without danger of breaking the cell.

This form of apparatus fulfilled all expectations, proving convenient, strong, and of quick action, as the results of Experiments No. 1 to 7, inclusive (see data which follows) show. Equilibrium was reached in from 10 to 12 hours and in even less time when the initial pressure was as much as half the equilibrium pressure. The so-called "Thermometer effects,"<sup>1</sup> which were so troublesome with the old type apparatus, proved negligible in the new form of cell. Solutions whose osmotic pressures are not over 100 atmospheres can be measured with ease and expediency in the apparatus as described. It was impossible, however, to get glass manometers which would withstand greater pressure than this. Experiment No. 5 was the only successful measurement of a higher pressure (124 atmospheres) and this could not be duplicated. In Experiment No. 7 a pressure of 165 atmospheres was recorded for a few hours before the manometer broke. Having strengthened the cell successfully, the problem resolved itself into a matter of securing a suitable means of measuring the higher pressures with a fair degree of accuracy.

The solution of this question was found in the electrical resistance<sup>2</sup> gage, the form adopted being that developed and used by Johnston and Adams in their work on high pressures at the Geophysical Laboratory, Carnegie Institution, Washington. They kindly lent one of their gages for this preliminary test of the method, and gave detailed instructions for the construction, calibration and use of this type of gage. The principle upon which this method of measuring pressure is based, is that the resistance of certain conductors to an electric current increases with pressure, the relation being very nearly linear. Pressures are measured by comparing the resistance of two similar resistance coils when both are subjected to the *same* pressure (that of the atmosphere), and again when one is subjected to the pressure to be determined. The change in resistance which the gage coil undergoes is a measure of the magnitude of the pressure in question.

The coils used in this instance were each made from 1 meter of No.

<sup>1</sup> *Pub. Carnegie Inst.*, No. 198.

<sup>2</sup> Lisell, Dissertation, Upsala, 1903; Lafay, *Compt. rend.*, 149, 566-569 (1909); Bridgman, *Proc. Am. Acad. Arts & Sci.*, 47, 11, 335 (1911); 49, 11, 640 (1913).

40 "Therlo" wire, double silk covered, wound noninductively upon a mica frame. This frame was made of two plates of mica intersecting each other at right angles. The coils were shellaced, baked, temperature seasoned at 150° for 16 hours, pressure seasoned at 1000 atmospheres for 24 hours, and at 8000 atmospheres for one-half hour. All joints to terminals and leads are silver soldered, to insure constancy of resistance.

"Therlo" is an alloy of copper, manganese and aluminium, and is used on account of its low temperature coefficient (+0.000056 per degree centigrade) and its negligible thermoelectric effect against copper. Compared with manganin, these factors are considerably smaller and the therlo has the further advantage of being more stable in its electrical and mechanical behavior. Its specific resistance is also higher than that of manganin.

The pressure coefficient of resistance for therlo is slightly more than two parts per million per atmosphere, the exact value depending upon the previous history.

The coils as made above have a resistance of about 100 ohms. Hence, in order to measure pressures accurately to  $\frac{1}{10}$  of an atmosphere it is necessary to have a means of measuring changes in resistance of one part in five million. This requirement is met in the Leeds and Northrup Carey Foster Bridge used with their new high sensitivity galvanometer. This outfit, when used with the 100 ohms coil above, has a sensitivity of 0.00001 ohm over a range of 0.01 ohm change in resistance, corresponding to a pressure range of 50 atmospheres; and a sensitivity of 0.0001 ohm over a range of 0.1 ohm change in resistance, corresponding to a pressure range of 500 atmospheres. The latter combination is the one used in this work,—however a plan is in mind for securing the greater sensitivity over the greater range and will be tried when such refinement seems justified.

The courtesy of the Geophysical Laboratory was extended to the authors who took advantage of the opportunity to calibrate this secondary gage against an absolute gage, in terms of resistance as measured by the Carey Foster Bridge. The calibration data follow in Table I.

TABLE I.

Pressure on absolute gage (atmos.).	Change in resistance of gage coil (ohms $\times 10^4$ ).			Change in resistance per atmos. (ohms $\times 10^4$ ).	Deviation from a change in resistance $2 \times 10^{-4}$ ohms per atmos. (ohms $\times 10^4$ ).

Additional value on last point	858.8				

For a working calibration curve the deviations given in the last column were plotted against the mean changes in resistance.

The details of construction of the gage as adapted for use in this work are shown in Fig. 2. Z is the coil described above, the terminals of which are hard soldered to the copper lead wires U and U'.

Fig. 2.

which the lead wires pass to the exterior and which screws into A' against the copper washer X. W and Y are packing to prevent leaks around the lead wires. W is composed of three layers of soapstone (alberine) carefully cut and drilled to fit the opening in V and the wires U and U'.

These soapstone plugs were forced into place by application of sufficient mechanical pressure to crush the stone and compress it securely in V tight around the wires. A knot was made in the wires between two of the layers of stone to prevent subsequent flowing of the copper under pressure. The exposed layer of stone was coated with marine glue and after drying a layer of molten Khotinsky wax (Y) was poured on. The function of the latter is chiefly to prevent movement of the lead wires, which causes a loosening of the soapstone around them. Some trouble with leakage on this account was experienced at first, but with the present arrangement there is none. The lead wires at the exterior end are hard-soldered to

heavy copper terminals S and S', which were amalgamated and dip into the mercury cups of the Carey Foster Bridge coil holder.

E' is the attachment by which the gage is connected to the osmotic pressure apparatus. The parts E' and F' in Fig. 2 correspond to parts E and F in Fig. 1 and serve as a means of connecting the resistance gage and the glass manometers respectively to the bronze cylinder J (Fig. 1). The coil Z is immersed in oil which fills the compartments in A' and E' as indicated by B'. The solution I (Fig. 1) is in contact with the oil at the lower end of the capillary opening in E' (Fig. 2). The compression

of the oil allows some of the solution to be forced up into this capillary. This necessitates frequent renewal of the oil. A mercury trap at the lower end of E' would obviate this difficulty. The comparison coil is immersed in oil in a brass cup and connected by means of mercury contacts to the other arm of the Carey Foster Bridge coil holder.

This gage presents many very decided advantages over the manometric method of measuring pressures. The strength is well nigh unlimited. The old type manometers, depending as they do upon the compression of a gas, involve a considerable change in volume. The only change in volume suffered in the resistance gage is that due to the compression of the oil. Hence dilution of the solution being measured is reduced to a minimum, and as a result, equilibrium is much more rapidly established. Furthermore the deviations of gases from Boyle's law make the manometric method less accurate at high pressures. The percentage error involved in reading the levels of the mercury menisci also increases with the compression of the gas to a small volume. So the higher the pressure the less sensitive the manometer becomes. On the other hand, the sensitivity of the resistance gage does not decrease with the pressure.

The results obtained with the modified osmotic pressure cell equipped with the resistance gage are most gratifying. Equilibrium is reached in from an hour and a half to six hours, depending upon the concentration of the solution and the initial pressure developed by compression of the rubber washers. This makes it possible to secure a satisfactory measurement within 24 hours. In this connection especial attention is called to Experiments Nos. 12, 18, 19, 20 and 22.

The objection raised by certain critics of the Morse and Frazer method, on the grounds that the solution is not stirred, may be legitimate in the case of these more concentrated solutions when measurements are completed in such a short time. The solutions are very viscous but the amount of water transferred into the solution is small and the area of the membrane is large. Hence it is but a thin film of water over the surface of the cell which must diffuse through the solution. As to whether or not stirring is essential can only be proven by trial. It is planned to introduce a stirring device into this form of apparatus in the near future and settle the question. Such an arrangement may at least hasten the establishment of equilibrium, although the speed with which equilibrium is apparently reached in the present apparatus leaves but little to be desired.

### Experimental.

**Preparation and Analysis of Solutions.**—This work was all done at 30° the apparatus, including the Carey Foster Bridge, being kept in a carefully regulated thermostat.

Aqueous solutions of cane sugar were studied over the complete range

of solubility. The sucrose used was carefully purified from rock candy. To facilitate ready comparison with previous work done in this laboratory, the solutions were all made up on the weight molar basis using atomic weights on the  $H = 1$  scale. The concentrations are expressed also in terms of  $O = 16$ . The sugar in each instance was dissolved in conductivity water made 0.01 ion normal with potassium ferrocyanide. The solvent against which the osmotic pressures were measured was 0.01 ion normal copper sulfate. The presence of the "membrane formers" repairs ruptures in the membrane made by the pressure. The specific gravity was determined for each solution; so that concentrations might also be expressed in terms of the volume molar system. This was for the purpose of comparison with measurements made by Berkley and Hartley and others who expressed the concentrations in terms of the volume molar system.

The extent to which the solutions were diluted during measurement was ascertained by the saccharimeter in the following manner:

From the optical rotation, the concentration was determined by reference to a curve made by plotting the values of the ratios of the concentrations of the original solutions to their optical rotations against *their* optical rotations, *i. e.*, letting  $C$  represent the concentration, and  $r$  the optical rotation, the values of  $C/r$  were plotted against the values of  $r$ . By multiplying the optical rotation of a given solution by the corresponding value of  $C/r$  as determined from the curve, the concentration of the solution in grams of sugar per 1000 g. of water was obtained.

In the work on dilute solutions carried on in this laboratory, corrections for changes in concentrations are made by changing the observed pressure the same per cent. that the optical rotation of the solution changes during the measurement. This involves two errors, for it assumes that the change in optical rotation is linearly proportional to the change in concentration and that the osmotic pressure is a linear function of the concentration. The magnitude of the error may be negligible in the case of dilute solutions but in the case of concentrated ones the error would be enormous. Hence in this work the final concentrations are determined from the curve described above and the observed osmotic pressures are recorded as the pressures of solutions of these concentrations.

The contents of the solvent compartment (L, Fig. 1) were examined after each experiment to determine to what extent the sugar had leaked through the membrane.

The amount of sugar in the "solvent" could not be detected by the saccharimeter in the case of experiments measuring pressures of solutions up to 5M concentration. In the experiments with the more concentrated solutions (5M and above), the solvent showed an optical rotation of  $0.5^\circ$ , which corresponds to an error in the measurement of the pressure of not more than 0.1 atmosphere and this is within the limits of accuracy

of the method at these pressures (150 to 250 atm.). In Experiments No. 16, No. 18 and No. 23, the leakage was somewhat more, due no doubt to the unseasoned conditions of the cells, as mentioned below. The results of these experiments are not considered of value.

### Results.

Table II gives a somewhat detailed account of representative experiments. From this can be seen the speed with which measurements can be obtained. Experiment No. 3 was made with a glass manometer, the others with the resistance gage.

In this table  $R$  is the resistance in ohms of the membrane.  $C$  is the original concentration of the solution expressed in weight molar terms ( $H = 1$ ).  $\alpha$  is the optical rotation of the solution after the experiment and  $c$  is its final concentration, expressed in grams of sugar per 1000 g. of water.  $t$  is the time that the reading was made, expressed in hours after the time at which the cell was set up.  $\Delta R$  is the change in resistance of the gage coil expressed in ten thousandths of an ohm (ohms  $\times 10^4$ ).  $P$  is the observed osmotic pressure.

A summary of the results of the experiments is given in Table III. This also includes data on molar and tenth molar solutions previously determined in this laboratory. The results of Experiments Nos. 5 and 7 with glass manometers are given no importance, for they were not duplicated. No. 7 not even being completed. The results of Experiments Nos. 13, 14, 16 and 18 are also given slight consideration for these were the first times that the cells used were ever subjected to such pressures. It has long been recognized that even at much lower pressures cells must be seasoned at a given pressure before they will develop the maximum osmotic pressure of a solution and give concordant results. Hence those measurements with unseasoned cells are disregarded. All other measurements are with cells more thoroughly seasoned by being set up with strong sugar solutions in the apparatus shown in Fig. 1, having A sealed off instead of sealed to a manometer.

In the last Experiment (No. 23) a supersaturated solution of cane sugar was used, in hopes of measuring the osmotic pressure of a saturated solution. The excess sugar was more than sufficient to saturate the water that would be taken up by the solution during the measurement.

<sup>1</sup> For previous work in this laboratory, see *Pub. Carnegie Inst.*, No. 198.

The pressure developed reached the maximum during the first few hours and then gradually decreased as the excess sugar in solution gradually crystallized out. Evidently equilibrium between solid and dissolved sugar was not reached during the experiment. It was impossible to get a satisfactory analysis of the solution by the saccharimeter. There was considerable leakage of sugar through the membrane so the results of the experiment are of no value save to show the greatest pressure developed.

In Fig. 3, the data in Table III are shown graphically. The curve AB was obtained by plotting the pressures ( $P$ ) against the concentrations ( $c$ ). AC is a theoretical curve in which the calculated pressures obtained from the thermodynamic formula for osmotic pressure are plotted against the concentration. These calculations neglect association of the solvent and hydration of the solute so are of no theoretical importance but simply show the extent of the deviation from ideal conditions.

Fig. 3.

From the Curve AB, the actual osmotic pressure of a solution of sucrose of any concentration may be determined by interpolation. More exact values may be obtained from a curve made by plotting the ratio  $P/c$  (Table III) against  $c$ . The interpolated values given in Tables IV and V were obtained from such a curve.

In Table IV the results of this work are compared with the data obtained by Berkley and Hartley<sup>1</sup> in their work on cane sugar. Their measurements were made at 0° (Col. 3), the concentrations being expressed in volume molar terms (Col. 1).

<sup>1</sup> *Trans. Roy. Soc., (A)* 206, 481 (1906).

By the help of the data in Table III the concentrations were transformed to the weight molar basis and are given in Col. 2. Assuming that the temperature coefficient of osmotic pressure is the same as for gas pressure, the values at 30° given in Col. 4 were calculated from the values of Berkley and Hartley determined at zero. In Col. 5 the data obtained in this laboratory are shown, these values being determined by interpolation as explained above. The concordance is really better than might be expected.

#### Discussion.

In calculating the theoretical values of osmotic pressure it has been customary in this laboratory to use the van't Hoff equation as modified by Morse and Frazer, *viz.*:

$$P = \frac{RT}{V} n \quad (1)$$

where P is the osmotic pressure, R is the gas constant and T the absolute temperature. V represents the volume of the pure solvent in the solution at 4°, and *n* represents the number of mols of solute present. This does very well for dilute solutions, but for more concentrated solutions the more exact thermodynamic formula should be used.

As early as 1894 it was pointed out by van der Waals and his associates Boldingh and van Laar, especially the latter,<sup>1</sup> that the properties of solutions (vapor pressure, osmotic pressure, etc.) are functions not of the relation of solute particles to solvent particles, but of solute particles to the total number of particles present, or more exactly, that the properties are a function of the mol fraction of the solvent present. This view and its relation to van't Hoff's equation has also been discussed at length by many other writers, namely, Gibbs, Evans, Trevor, Lewis, and Washburn, in particular.

Van Laar's equation for the relation between osmotic pressure and concentration is

$$P = \frac{-RT}{V_0} \ln \frac{N}{N + n} \quad (2)$$

<sup>1</sup> Van Laar, *Zeit. Phys. Chem.*, 15, 457 (1894).

where  $V_o$  = the molar volume of the solvent,  $N$  = the number of mols of the solvent and  $n$  = the number of mols of the solute. If the thermodynamic relation between vapor pressure and osmotic pressure expressed by the familiar equation,

$$P = \frac{RT}{V_o} \ln \frac{p_o}{p} \quad (3)$$

is accepted, then Equation 2 follows directly from a consideration of Raoult's law.

In other words, Raoult's law states that the vapor pressure of a solution is a function of the mol fraction of the solvent present, so if there is a direct relation between vapor pressure and osmotic pressure, the latter must also be a function of the mol fraction of solvent present.

The above mentioned writers also point out that the value of Equation 1 lies in its being an approximation of Equation 2 for if  $x$  is used to represent the mol fraction of the solute present, Equation 1 may be expressed,

$$P = \frac{RT}{V_o} (x + x^2 + x^3 + \dots) \quad (4)$$

Equation 2 upon expansion becomes,

$$P = \frac{RT}{V_o} (x + \frac{1}{2}x^2 + \frac{1}{3}x^3 + \dots) \quad (5)$$

and it will be seen that the two equations differ only in the higher powers of  $x$ . If this factor is small the higher powers may be neglected and the two equations become identical.

Equation 1, as an approximation of Equation 2, gives values practically identical with those obtained from the latter in the case of dilute solutions. However, as the concentration of the solution increases, the values as calculated from the two equations differ more and more. Hence Equation 2 alone can be used correctly in the case of concentrated solutions. This has been done in all calculations in this paper.

At the pressures measured in this work the compressibility of the solution is no doubt an important factor. However, no data was available so this factor was neglected.

In the case of aqueous solutions the degree of association of the solvent must be considered as well as the hydration of the solute.

For weight normal solutions  $N = \frac{1000}{18.015.a}$  where  $a$  is the degree of association of the solvent. If we represent the degree of hydration of the solute by  $W$ , then

$$N = \frac{1000}{18.015.a} - \frac{W}{a} n$$

and the mol fraction of solvent present

$$\frac{N}{N+n} - \frac{\frac{1000}{18.015a} - \frac{W}{a} n}{\left(\frac{1000}{18.015a} - \frac{W}{a} n\right) + n}$$

The molecular volume of the solvent is equal to the volume ( $v$ ) of one gram of the solvent at the temp. ( $t$ ) multiplied by its molecular weight.

$$V_0 = v \cdot 18.015a$$

The value of  $R$  in cc. atmospheres is 82.07. Making these substitutions and introducing the factor for transference from natural to Briggsian logarithms we have as the final working form of the equation

$$P = \frac{-82.07(273.1 + t^\circ)2.303}{v \cdot 18.015a} \log \frac{\frac{1000}{18.015a} - \frac{W}{a} n}{\left(\frac{1000}{18.015a} - \frac{W}{a} n\right) + n} \quad (6)$$

No reliable data are available for the degree of association of water. However, it is the consensus of opinion<sup>1</sup> that water is a ternary mixture of mono-, di- and tri-hydrol, the di-hydrol predominating. The equilibrium, however, is greatly influenced by temperature and pressure. Increases in the former shift the equilibrium towards the mono-hydrol and increases in pressure shift the equilibrium toward the di-hydrol. So in the absence of exact figures the degree of association has been taken as 2.

Using the factors indicated in Equation 6,  $n$  must be expressed as the weight molar concentration in terms of  $O = 16$ .

Table V gives a comparison of the experimental values of osmotic pressure compared with the calculated values, assuming the various degrees of hydration indicated.

In Column 2 are found the experimental values of osmotic pressure  $P$  and in Column 3 are shown the values of "molecular pressure" at each

<sup>1</sup> Walden, *et al.*, *Trans. Far. Soc.*, 6, 71 (1910).

concentration (*i. e.*, the pressure per mol of sugar, neglecting hydration). It will be noted that these figures approach a constant value as saturation is approached.

In Columns 4 and 5 a comparison is made of the values of  $P$  as calculated by Equation 1 and by Equation 2, association and hydration both being neglected.

The curve AC in Fig. 3 is of the values in Column 5 and shows by comparison with the experimental curve AB how greatly the complications of the associations of solvent and the hydration of the sugar cause the results to deviate from ideal conditions.

Column 6 gives the values obtained when the assumption is made that a hexahydrate of constant composition is formed and that the effect of association on the results obtained is negligible. It is upon these assumptions that Washburn<sup>1</sup> bases his consideration of calculated osmotic pressures. While the concordance with the observed values is fair at lower concentrations it is obvious that the errors are considerable at higher concentrations.

Columns 7, 8 and 9 show the values obtained from Equation 6, assuming the degree of association of water as 2 and assuming the formation of the hexa-, penta- and tetrahydrates, respectively. From a consideration of Column 7 it will be seen that even when the degree of association is taken into account, the assumption that a hexahydrate is formed which is stable throughout the entire range, is unwarranted. Similarly, from Column 8, it will be seen that the assumption of Callendar,<sup>2</sup> that a stable pentahydrate exists throughout the range, is also open to objection. Both of these assumptions, however, seem to hold over limited ranges, but now that the entire range of solubility has been studied, the evidence indicates a change in the degree of hydration with changes in concentration. Up to concentrations of 2 molar, calculations based on the assumption of the formation of the hexahydrate, give results most concordant with the experimental values. At two molar concentration the experimental value is a mean between values obtained theoretically, considering the formation of hexa- and pentahydrates, respectively.

For 3 and 4 molar concentrations the assumptions of the existence of the pentahydrate gives values concordant with experimental results. At 5 and 6 molar concentrations the experimental values are intermediate between those obtained assuming the degree of hydration as five, and those assuming the hydration as four.

The extrapolated experimental value for 6.5 molar (which is practically a saturated solution) concords well with the calculated value

<sup>1</sup> "Principles of Phys. Chem.," McGraw-Hill, 1915.

<sup>2</sup> *Proc. Roy. Soc., (A)* 80, 466 (1908).

for the tetrahydrate. Hence it would seem that the degree of hydration of cane sugar in aqueous solutions decreases gradually with increase in concentration. This is in harmony with the newer hydrate theory of Jones.<sup>1</sup> Findlay,<sup>2</sup> in his discussion of osmotic pressure considers the experimental data formerly available as evidence against Jones' hydrate theory and harmonizing with the older one of Mendeleef. His conclusions, as well as those of Washburn and Callandar were simply based on considerations of too limited ranges of concentration.

### Summary.

I. In this article the authors describe a modification of the Morse and Frazer method of measuring Osmotic Pressures. The principal features of the new apparatus are: first, the reversal of the position of the semi-permeable membrane such that the pressure is developed around the outside of the porous clay cell; second, the use of an electrical resistance gage for measuring the magnitude of the pressures developed.

II. It is pointed out that this apparatus is a decided improvement over the old, and that it is much stronger and much quicker in its action. Pressures of at least 270 atmospheres can be measured and equilibrium is reached in a few hours so that measurements are completed in from 12 to 24 hours. These features make the method applicable to a study of concentrated solutions, and, it is hoped, to a study of solutions of certain electrolytes.

III. Measurements of the osmotic pressures of cane sugar solutions over the complete range of solubility are given and the results compared with those of other investigators over limited ranges.

IV. In the theoretical discussion the Morse and Frazer modification of van't Hoff's equation is compared with van Laar's thermodynamic equation, using the mol fraction basis. The necessity of using the latter in calculating the osmotic pressures of concentrated solutions is recognized by the authors, as has been done by others.

The experimental values obtained are compared with the theoretical values calculated by means of van Laar's equation, assuming various degrees of hydration of the dissolved sugar. It is pointed out that, although the theoretical calculations are based on assumptions and neglect certain factors, the evidence indicates that the hydrates of cane sugar formed in aqueous solutions are not of constant composition, as some have thought, but are of variable composition. The degree of hydration decreases with increase in the concentration of the sugar.

## REACTIONS IN NON-AQUEOUS SOLVENTS. I. THE ACTION OF CHROMYL CHLORIDE UPON THE PHOSPHORUS TRIHALIDES.

BY HARRY SHIPLEY FRY AND JOSEPH L. DONNELLY.

Received July 21, 1916.

## A. Interaction of Chromyl Chloride and Phosphorus Trichloride.

The action of chromyl chloride upon phosphorus trichloride has received very little attention. This may be due to the explosive nature of the reaction, concerning which A. Michaelis has written:<sup>1</sup>

"Chromacichlorid darf man wegen der Heftigkeit der Einwirkung nur tropfenweise zu stark abgekühlten Phosphorchlorür fließen lassen. Jeder Tropfen verursacht lebhaftes Zischen und Feuererscheinung, die jedoch nur zuerst sichtbar ist, indem sich die Retorte bald mit einem undurchsichtigen blaugrünen Anflug beschlägt. Die letzten Tropfen verursachen zuweilen Detonation. Die Reaction verlief nach der Gleichung:

"Indem aber das Phosphorsuperchlorid theilweise auf das Anhydrid einwirkte, entstand noch mehr Oxychlorid:

Since these equations have not been substantiated by quantitative data, a study of the interaction of chromyl chloride and phosphorus trichloride under new and safer conditions is of moment.

When solutions of chromyl chloride and phosphorus trichloride in *anhydrous carbon tetrachloride* are mixed there is formed at once a dark brown gelatinous precipitate which, when filtered off, washed with carbon tetrachloride and dried in a current of air free from moisture and carbon dioxide, was a finely divided gray-green powder, too deliquescent to be examined microscopically. It reacted with water (exothermic reaction) and the dark green aqueous solutions gave reaction for the following ions:  $\text{H}^+$ ,  $\text{Cl}^-$ ,  $\text{Cr}^{+++}$  and  $\text{PO}_4^{---}$ .

If the carbon tetrachloride solution of phosphorus trichloride is added slowly to the carbon tetrachloride solution of chromyl chloride, the volume of the precipitate increases but the color of the red chromyl chloride gradually fades to yellow and eventually becomes colorless when an excess of the phosphorus trichloride has been added. Then, of course, further additions of the trichloride yielded no more precipitate. These facts suggested the possibility of studying the reaction volumetrically provided that the end point of the reaction could be determined satisfactorily.

An accurate determination of the end point was made possible by applying a new reaction<sup>2</sup> for the detection of minute traces of chromyl

<sup>1</sup> *Jahresb. Chem.*, 1871, 248.

<sup>2</sup> Fry, "Notes on the Preparation of Chromyl Compounds," *THIS JOURNAL*, 33, 697 (1911).

chloride in carbon tetrachloride solution which depended upon the formation of the unstable but intensely colored *chromyl bromide* according to the equation<sup>1</sup>

Fry found that the addition of one drop of acetyl bromide to a 0.001 molar solution of chromyl chloride in carbon tetrachloride gave an intense violet-red coloration permanent for about five minutes. Thus it is possible to titrate standard solutions of chromyl chloride and phosphorus trichloride in carbon tetrachloride to an accurate end point which is conveniently determined by removing a small drop of the reaction mixture on the end of a stirring rod and mixing it with a drop of the indicator, acetyl bromide, on a tile plate. The excessive fuming of the acetyl bromide may be modified by diluting it with carbon tetrachloride. This dilution does not interfere with the violet-red end point coloration.

In order to ascertain the molecular ratios in which chromyl chloride and phosphorus trichloride interact, 0.2 molar solutions of these compounds in carbon tetrachloride were prepared and immediately titrated from burets into 300 cc. Erlenmeyer flasks containing 100 cc. of carbon tetrachloride. An average of four titrations gave the interesting ratio in which 2 volumes of 0.2 molar  $\text{CrO}_2\text{Cl}_2$  solution were equivalent to 3.02 volumes of 0.2 molar  $\text{PCl}_3$  solution. This is practically a 2:3 ratio, i. e.,  $2\text{CrO}_2\text{Cl}_2:3\text{PCl}_3$ . The following equation, based upon this ratio, was assumed to represent the reaction in question:

The properties of the compound formed, and its analysis (described below) indicated that its composition may be represented by the formula  $\text{CrOCl}.\text{POCl}_3$ . It is decomposed by atmospheric moisture with evolution of hydrochloric acid fumes. Its decomposition by water, yielding a solution containing hydrogen-, chlorine-, chromic- and phosphate-ions, indicates that the hydrolysis may be represented by the equation

The ready and complete hydrolysis of the compound facilitated the analysis for its chromium and chlorine contents.

**Determination of Chromium.**—Weighed samples of the compound were dissolved in water.  $\text{Cr}^{+++}$  was oxidized to  $\text{CrO}_4^{--}$  by addition of sodium peroxide. Titration with standard ferrous ammonium sulfate solution gave the following results:

Substance (g.).	0.1 N ferrous soln. (cc.).	% Cr. Found.	% Cr. Theory.
0.3587	41.79	20.12	20.26
0.7109	82.70	20.14	.....

<sup>1</sup> The existence of chromyl bromide has been indicated in three other reactions, namely:  $\text{CrO}_3 + 2\text{HBr} \longrightarrow \text{CrO}_2\text{Br}_2 + \text{H}_2\text{O}$ ;  $\text{CrO}_2\text{Cl}_2 + 2\text{HBr} \longrightarrow \text{CrO}_2\text{Br}_2 + 2\text{HCl}$ ;  $(\text{HO})_2\text{CrO}_2 + 2\text{CH}_3\text{COBr} \longrightarrow \text{CrO}_2\text{Br}_2 + 2\text{CH}_3\text{COOH}$ . (Fry, *Loc. cit.*)

(The chromium was also determined by the sodium peroxide fusion method with equally concordant results.)

**Determination of Chlorine.**—Weighed samples were dissolved in water. After addition of nitric acid the chlorine was precipitated and weighed as silver chloride with the following results:

Substance (g.).	AgCl (g.).	% Cl. Found.	% Cl. Theory.
0.3938	0.8680	54.53	54.98
0.2372	0.5247	54.72	.....

Invariably, minute quantities of hydrogen chloride were lost when the compound was decomposed with water, which accounts for the slightly lower percentage of chlorine than that demanded by the theory. Nevertheless, the preceding analysis for the contents of chromium and chlorine indicate that the composition of the compound may be represented by the formula  $\text{CrOCl} \cdot \text{POCl}_3$ . Further confirmation of this formula was afforded by igniting weighed samples of the compound in porcelain crucibles, assuming that decomposition proceeded according to the equation

or to the equivalent equation

Accordingly, the residue obtained after ignition should correspond in composition to the formula  $\text{CrOCl}$  or  $\text{Cr}_2\text{O}_3 \cdot \text{CrCl}_3$ , the volatile component of the original compound being  $\text{POCl}_3$ . This is indicated by the following data:

Substance.	Residue, $\text{CrOCl}$ .	% $\text{CrOCl}$ . Found.	% $\text{CrOCl}$ . Theory.
0.3102	0.1228	39.52	40.23
0.5702	0.2252	39.48	.....

The dark green residue was insoluble in water and in concentrated acids. It was analyzed for its chromium content by the sodium peroxide fusion method with the following results:

Substance.	0.1 N ferrous soln., cc.	% Cr. Found.	% Cr. Theory.
0.2789	80.40	49.84	50.26
0.3509	100.55	49.78	.....

The amount of the residue left upon ignition and the percentage of chromium in the residue indicates that the insoluble product of the interaction of chromyl chloride and phosphorus trichloride in carbon tetrachloride solution may be represented by the formula  $\text{CrOCl} \cdot \text{POCl}_3$ . Furthermore, the reaction for its formation has been shown to involve 2 molecules of  $\text{CrO}_2\text{Cl}_2$  to 3 molecules of  $\text{PCl}_3$ . Hence the equation for the reaction

is warranted by the quantitative study herewith presented in Part A.

## B. Interaction of Chromyl Chloride and Phosphorus Tribromide.

Nothing was found in the literature relative to the interaction of chromyl chloride and phosphorus tribromide. When minute quantities of the pure substances are brought together the reaction takes place with explosive violence. Therefore, it is desirable to modify the reaction by dissolving the chromyl chloride and the phosphorus tribromide in anhydrous carbon tetrachloride, and to study quantitatively the interaction in the same way that the interaction of chromyl chloride and phosphorus trichloride was investigated in the preceding Part A. Here also, upon titration, one-fifth molar solutions of chromyl chloride and the phosphorus trihalide were found to interact completely in the ratio of two volumes of the former to three volumes of the latter, *i. e.*,  $2\text{CrO}_2\text{Cl}_2 : 3\text{PBr}_3$ . The end point of the reaction was readily determined by the formation of *chromyl bromide* using acetyl bromide as the indicator reagent on the porcelain tile as previously described. On the basis of the above ratio (2 : 3) the following equation was assumed for the reaction in question:

This equation is perfectly analogous to the equation for the interaction of  $\text{CrO}_2\text{Cl}_2$  and  $\text{PCl}_3$  in Part A.

The product of the interaction (presumably  $\text{CrOCl}.\text{POBr}_3$ ) after being filtered, washed repeatedly with carbon tetrachloride and dried in a current of air free from moisture and carbon dioxide, was a finely divided purple-gray powder. Its extremely deliquescent properties made it difficult to handle and prevented, with the resources at hand, a much desired microscopic examination. Its exothermic decomposition with water proceeded vigorously and the resulting green solution gave reactions for hydrogen-, chlorine-, bromine-, chromic- and phosphate-ions. Accordingly the hydrolysis may be represented by the following equation:

The solubility of the products of hydrolysis of the compound in question ( $\text{CrOCl}.\text{POBr}_3$ ) facilitated its analysis (according to methods described in Part A) for the chromium and halogen contents. The data for the chromium determinations are as follows:

Substance (g.).	0.1 N ferrous soln. (cc.).	% Cr. Found.	% Cr. Theory.
0.2310	18.45	13.83	13.34
0.3167	25.15	13.75	.....

The determination of the halogens in the compound involved the simultaneous precipitation of silver bromide and silver chloride in the molecular ratio  $3\text{AgBr} : \text{AgCl}$ . This is the ratio demanded by the assumed formula of the compound and by the equation for its hydrolysis. The assumption and formula are verified by the following analysis:

Substance (g.).	Found $\text{AgCl}3\text{AgBr}$ (g.).	Theory $\text{AgCl}3\text{AgBr}$ (g.).
0.5607	1.0238	1.0122

The results of the chromium and halogen determinations indicate that the composition of the compound may be represented by the formula  $\text{CrOCl} \cdot \text{POBr}_3$ , but its behavior upon ignition was not altogether similar to that of the preceding compound,  $\text{CrOCl} \cdot \text{POCl}_3$ , which yielded a residue corresponding in composition to the formula  $\text{CrOCl}$  or its equivalent  $\text{Cr}_2\text{O}_3 \cdot \text{CrCl}_3$ . The compound now in question,  $\text{CrOCl} \cdot \text{POBr}_3$ , yielded on ignition a purple residue which corresponded in quantity to a compound of the formula  $\text{CrOBr}$  or its equivalent,  $\text{Cr}_2\text{O}_3 \cdot \text{CrBr}_3$ , as shown by the following data:

Substance (g.).	Residue (g.).	% CrOBr. Found.	% CrOBr. Theory.
0.5002	0.1878	37.55	37.90
0.4546	0.1708	37.57	.....

This purple residue, insoluble in water and in concentrated acids, was analyzed for its chromium content by the sodium peroxide fusion method. The results of this analysis also indicate that the composition of the residue may be represented by the formula  $\text{CrOBr}$  or  $\text{Cr}_2\text{O}_3 \cdot \text{CrBr}_3$ .

Substance (g.).	0.1 N ferrous soln. (cc.).	% Cr. Found.	% Cr. Theory.
0.2076	42.25	35.37	35.16
0.2542	52.05	35.40	.....

Therefore, in conformity with the preceding analyses, the decomposition of the compound upon ignition may be represented by the equation

In conclusion, it may be noted that the reactions for the formation and the reactions for the decomposition of the compounds  $\text{CrOCl} \cdot \text{POCl}_3$  and  $\text{CrOCl} \cdot \text{POBr}_3$  are analogous.

### Summary.

1. The dangerously explosive interaction between chromyl chloride and the phosphorus trihalides can be controlled and investigated quantitatively by conducting the reactions in the anhydrous solvent carbon tetrachloride.

2. Equimolar solutions (0.2 molar) of chromyl chloride and phosphorus trihalide were found to interact in the ratio of two volumes of the former to three volumes of the latter, *i. e.*,  $2\text{CrO}_2\text{Cl}_2 : 3\text{PX}_3$  ( $\text{X} = \text{Cl}$  or  $\text{Br}$ ).

3. The determination of this ratio by volumetric methods was rendered possible through the use of acetyl bromide as an indicator for the detection of minute traces of chromyl chloride, the end point of the reaction depending upon the formation of the unstable but intensely colored (violet-red) *chromyl bromide*.<sup>1</sup>

4. The new compounds thus prepared correspond in composition to the formulas  $\text{CrOCl} \cdot \text{POCl}_3$  and  $\text{CrOCl} \cdot \text{POBr}_3$ . They yielded on ignition compounds corresponding to the formulas  $\text{CrOCl}$  (or  $\text{Cr}_2\text{O}_3 \cdot \text{CrCl}_3$ ) and  $\text{CrOBr}$  (or  $\text{Cr}_2\text{O}_3 \cdot \text{CrBr}_3$ ), respectively.

<sup>1</sup> Fry, *THIS JOURNAL*, 33, 697 (1911).

5. The interactions between chromyl chloride and the phosphorus trihalides are essentially oxidation-reduction processes as shown by the composition and properties of the compounds formed. The general equation for the reactions, namely,

indicates reduction of the hexavalent chromium compound to trivalent chromic compounds and the oxidation of trivalent phosphorus halides to pentavalent phosphorus compounds. Thus, on the basis of the established 2 : 3 ratio, the above equation reduced to its simplest term becomes

## THE INFLUENCE OF THE POTASSIUM ION AND OF THE CALCIUM ION UPON THE FERRI-FERRO-CYANIDE POTENTIAL.

BY EUGENE P. SCHOCH AND WILLIAM A. FELSING.

Received February 2, 1916.

OUTLINE.—1. Review of Previous Investigations. 2. Outline of Work Done and Results Attained. 3. Experimental Details and Calculation of Results. 4. Theoretical Considerations: (a) Significant Values of  $n$  and  $k$  for Ferricyanides and Ferrocyanides. (b) The Relation between the Activities and the Concentrations of the Ferricyanides and Ferrocyanides. 5. Summary.

### Review of Previous Investigations.

The earliest measurements of the potential of the ferri-ferrocyanide<sup>1</sup> electrode were made by Schaum<sup>2</sup> and showed a dependence of the potential upon the concentration represented by Peters' modification of the Nernst formula

$$E_{\text{obs.}} = E_k + 0.0002 T \log \frac{[\text{total ferricyanide}]}{[\text{total ferrocyanide}]}$$

A little later (1902) Fredenhagen<sup>3</sup> obtained the same result.

However, the result announced by these investigators is not true in general but it is only true for a series of solutions in which the total ion concentration is constant. This was shown conclusively by Lewis and Sargent,<sup>4</sup> who made a rigorous test of the rule of mixtures by making up mixtures with constant potassium ion concentrations, but different ferri-ferrocyanide concentrations, and measuring their potentials. These

<sup>1</sup> The term "ferri-ferrocyanide" is used in this paper to denote any mixture containing both potassium (or calcium) ferricyanide and potassium (or calcium) ferrocyanide with or without the chloride of the same metal.

<sup>2</sup> *Z. Elektrochem.*, 5, 316 (1899); see also *Ibid.*, 9, 406 (1903).

<sup>3</sup> *Z. anorg. Chem.*, 29, 398 (1902).

<sup>4</sup> *THIS JOURNAL*, 31, 355 (1909).

solutions were made by adding very small amounts of ferrocyanide and ferricyanide to solutions with relatively high concentrations of potassium chloride. The authors found that, as long as the  $K^+$  ion concentration was kept constant, variations of the potential obtained by varying the ratio of the ferrocyanide to the ferricyanide concentration agreed to 0.1 millivolt with the differences calculated with the Nernst-Peters formula above.

Lewis and Sargent showed also that variations in  $K^+$  ion concentration affect the ferri-ferrocyanide potentials very extensively, an increase in potassium ion concentration making the potential more positive. The amount of this change is much greater than the change of potential calculated from the change in the ratio of the concentrations of free ferricyanide to free ferrocyanide ions if the latter are calculated from conductivity ratios.

E. Mueller<sup>1</sup> has shown recently that the influence of the potassium ion upon the potential of mixtures with high concentrations of potassium ion is expressed by the following formula:

$$E_{\text{obs.}} = E_k + 0.0002 T \log \frac{[\text{total ferri.}] \times [K^+]}{[\text{total ferro.}]}$$

This relation Mueller found to be true for ferro-ferricyanide solutions which are from 0.2 to 1.0 *N* with respect to potassium chloride, but it is not true for more dilute solutions.

The foregoing presents the latest work upon the subject of this paper which has come to our notice.

### Outline of Work Done and Results Attained.

In order to gain farther insight into the concentration relations in ferri-ferrocyanide mixtures, we prepared two series of mixtures and measured their specific conductivities, and their potentials against a standard electrode. In one series, the mixtures contained only potassium ferricyanide and potassium ferrocyanide, while in the other series the mixtures contained potassium chloride in addition to these salts. The concentrations of the two or three salts in the mixtures are given in Table II at the end of the next section of this paper. Both series begin with very dilute mixtures, and extend to moderately concentrated mixtures, and the relative proportions of the two or three salts are varied extensively. The experimental details of this work are presented in the next section of this paper, and the results of the measurements are given in Table II.

The calculation of the concentrations of the ions and of the un-ionized molecules in these mixtures was made under the assumption that intermediate ions are not formed, and that the degrees of ionization are given

<sup>1</sup> *Z. physik. Chem.*, **88**, 46 (1914).

by the conductivity ratios of the salts. But before this could be done, it was necessary to determine the conductivity-concentration curves of potassium ferrocyanide and of potassium ferricyanide, and to obtain from these the ionic conductances of the ferrocyanide ion and of the ferricyanide ion. The values obtained for the latter were checked by the determinations from calcium ferrocyanide and calcium ferricyanide. The conductivity data for these salts are given in Table I at the end of the next section. All concentrations in this article for which the concentration units are not stated are expressed in milli-equivalents per liter!

With these conductivity data, the concentrations of the ions in the ferri-ferrocyanide mixtures were then calculated by a method which has been described by Sherrill<sup>1</sup> and others. The results of these calculations are given in Table II.

In order to determine whether or not the rule of "isohydric" mixtures holds with mixtures containing salts of the uni-trivalent and uni-quadrivalent types, the specific conductances of these mixtures were measured and compared with values calculated on the basis of these assumptions.

A comparison of the calculated with the observed conductances of these mixtures (see Table II, last two columns) reveals that for nineteen out of the twenty-eight mixtures these two values either agree very closely, or the calculated values are higher by less than 1%. In four other mixtures (Nos. 14, 17, 21, and 22) the calculated values are nearly 2% higher than the observed; and in Mixtures 9, 10, 23, 27, and 28 the calculated values are from 2 to 3% higher than the observed.

The observed conductances of Mixtures 1-8 and 13-22 inclusive are more dependable than the others because they were checked, not only with mixtures made from the same stock solutions, but also with mixtures made from different stock solutions. For ten of these eighteen mixtures, the calculated conductances exceed the observed by less than 0.5%; for four others, the calculated conductances exceed the observed by about 1%, and for the remaining four, the calculated values exceed the observed by a little less than 2%. The duplication with mixtures from different stock solutions served to eliminate several observed values which differed by more than 2% from the calculated values, and hence it is likely that similar duplication with Mixtures No. 9, 10, 23, 27, and 28 would reduce the differences between their calculated and observed conductances to less than 2%.

The agreement between the calculated and observed conductances of these mixtures is sufficiently close to justify the conclusion that the rule of mixtures holds for mixtures of salts of the uni-trivalent and uni-quadrivalent types.

<sup>1</sup> THIS JOURNAL, 32, 741 (1910).

Since the difference between the potentials of the two ferri-ferrocyanide mixtures is much larger than the potential difference calculated from these "calculated" concentrations of the ferricyanide ion and ferrocyanide ion by means of the Nernst-Peters formula

$$E_{(25^{\circ} \text{ C.})} = E_k + 0.0591 \log \frac{[\text{ferricy. ion}]}{[\text{ferroc. ion}]},$$

and since it is known that the potential also depends upon the concentration of the potassium ion, the idea naturally presented itself to introduce in this formula, under the logarithm, the concentration of the potassium ion raised to a power,  $x$ , which is to be determined by trial. Thus modified, the formula has the form,

$$E_{\text{obs. } 25^{\circ} \text{ C.}} = E_{k_1} + 0.0591 \log \frac{[\text{ferricy. ion}] \times [\text{K}^+]^x}{[\text{ferroc. ion}]} \quad (I)$$

With the concentrations of the ferrocyanide, ferricyanide, and potassium ions expressed milliformal, it was found that values of  $x$  extending from 0.725 to 0.750 gave fairly constant values for  $E_{k_1}$ . The variations in the values of  $E_{k_1}$  obtained with different values of  $x$  extending from 0.6 to 0.8 are shown in Table IV. With  $x = 0.725$  the maximum difference between individual  $E_{k_1}$  values is 4.3 millivolts; with  $x = 0.75$  it is 4.4 millivolts; while with other values of  $x$ , the maximum differences between individual  $E_{k_1}$  values are much greater.

Concerning the choice of the value of  $x$ , we observe the following: the  $E_k$  values obtained with  $x = 0.725$  or 0.750 show no progression with  $\Sigma i$  either in the series of the mixtures without potassium chloride or in the series with it; and with all kinds of mixtures the different values show equal variations on both sides of the mean. The  $E_k$  values obtained with larger or smaller values of  $x$  differ from those obtained with  $x = 0.725$  or 0.750 by the amount

$$dE_k = (0.725 \text{ or } 0.750 - x) 0.0591 \log [\text{K}^+]$$

and hence they present series of values progressing with  $\Sigma i$ . It is evident that the attempt to use  $x$  values other than 0.725 or 0.750 together with a change in  $x$  proportionate to  $\Sigma i$  and intended to eliminate the value of  $dE_k$ —that this attempt would give the same relation that a constant  $x$  would give. Hence  $x$  is considered to be constant and equal to 0.725 to 0.750.

The maximum variation of 4.3 millivolts, which the values of  $E_{k_1}$  corresponding to  $x = 0.725$  present, is not large in comparison with the total range of 152 millivolts in the potentials of the mixtures, particularly in view of the fact that the compositions of the mixtures present a range of total potassium ion concentration (or  $\Sigma i$ ) extending from 7.85 to 395 millions per liter.

In order to ascertain the nature of the causes which produce these

variations in  $E_h$ , we should note that the mixtures which contain only ferricyanide and ferrocyanide (Nos. 1 to 12, inclusive) show variations in  $E_h$  of the same extent and kind as mixtures which contain these two salts in relatively small concentrations together with potassium chloride in relatively great concentrations (Nos. 13 to 20, inclusive).

An idea of the extent to which the contact potentials in these cells may affect the observed potentials can be obtained by a comparison of some of these. Since the equivalent conductance of the ferrocyanide ion at 25° is 111 mhos, that of the ferricyanide ion 93.2 mhos, and that of the potassium ion 74.8 mhos, it follows that the contact potential between a solution containing mainly potassium ferrocyanide and the solution of potassium chloride in the calomel electrode (as in Nos. 9 and 11) will be greater than the contact potential between a solution containing mainly potassium ferricyanide—but with the potassium ion of the same concentration as in the ferrocyanide solution—and the same calomel electrode (as in Nos. 10 and 12, respectively). These contact potentials act in such a sense as to *increase* the observed potentials of the cells, because the ferri-ferrocyanide poles are positive to the calomel electrode; and in accordance with these considerations, we find that the  $E_h$  value of No. 9 is 0.7 millivolt greater than that of No. 10, while that of No. 11 is 2.1 millivolts greater than that of No. 12. Again, the contact potential between the calomel electrode and any particular one of our solutions containing mainly potassium chloride should be less than that between the same calomel electrode and any of our ferri-ferrocyanide mixtures containing no potassium chloride but with the potassium ion of the same concentration as the particular "potassium chloride" solution selected: this is shown to be the case with Nos. 8 and 18 (difference 2.7 millivolts), Nos. 4 and 15 (difference 2.9 millivolts), Nos. 5, 16, and 22 (difference 2.2 millivolts), Nos. 7 and 17 (difference 0.4 millivolt). These observations indicate the amount of variation due to the contact potential, and they also indicate that the variations in the values of  $E_h$  are due largely, if not entirely, to the contact potential. In any case, the variations not thus accounted for do not exceed 2 millivolts, and they affect the two series of mixtures—*i. e.*, with and without potassium chloride—alike.

The average value of  $E_h$ —the normal potential—obtained with  $x = 0.75$  is + 0.0526 volt. With  $x = 0.725$ ,  $E_h$  is equal to +0.0554. This is the potential of the ferro-ferricyanide electrode with all active components at unit concentrations, with this electrode measured against the "normal" calomel electrode, at 25°, and with a saturated potassium chloride solution between the two electrode liquids. Since in the general formula the expression under the logarithm contains two concentration factors in the numerator, but only one in the denominator, the numerical value obtained from the formula depends upon the units in which the

molecular concentrations are expressed. The  $E_{h_1}$  values presented in this paper are obtained by expressing concentrations in millimols per liter; hence if they were expressed in mols per liter, the  $E_{h_1}$  value would be different by an amount equal to  $0.0591 \log 1000 = 0.1773$  volt, and its value would be

$$E_{h_1} = +0.0526 + 0.1773 = +0.2299 \text{ volt, if } x = 0.75,$$

or

$$= +0.0554 + 0.1773 = +0.2327 \text{ volt, if } x = 0.725.$$

It should also be noted that this  $E_{h_1}$  value is, as it should be, different from the ordinary "normal" potential which is 0.4 volt, as given by Abegg, Auerbach and Luther.<sup>1</sup> The latter value rests upon the assumption that the ferrocyanide and ferricyanide ions alone affect or determine the potential. In reality, however, Abegg, Auerbach, and Luther's value is obtained only with a certain concentration of potassium ion, and hence is really not a *normal* potential.

Since the pole reaction in these ferri-ferrocyanide mixtures may also be expressed as follows:

it was to be expected that the potential may be expressed as a function of the un-ionized ferricyanide and ferrocyanide, together with some power of the potassium ion concentration.

It was found that the formula

$$E_{\text{obs. } 25^\circ} = E_{h_2} + 0.0591 \log \frac{[K\text{-ferricy.}-U] \times [K^+]^y}{[K\text{-ferroc.}-U]} \quad (II)$$

gives fairly constant  $E_{h_2}$  values when  $y = 0.675$ .

The "mean" values, obtained with various values of " $y$ " and with the concentrations of the substances expressed "milli-formal" are presented in Table IV. The mean  $E_{h_2}$  value obtained with  $y = 0.675$  is  $+0.0753$  and the maximum difference between individual  $E_{h_2}$  values is 6 millivolts.

In order to throw further light upon the relation of the "cation" concentration upon the ferri-ferrocyanide potential, this work with the potassium salts was repeated with the corresponding calcium salts. Special experimental details concerning the preparation of these salts, etc., are given below, under a separate heading, together with other experimental details. The conductivity data for the separate calcium salts are given in Table I, and the data for the mixtures of calcium salts are given in Table III.

A glance at the last two columns in Table III reveals that the observed and the calculated specific conductivities of the mixtures of calcium salts agree fairly well with each other and thus corroborate the results obtained with the potassium salt mixtures.

<sup>1</sup> *Abh. Bunsen Ges.*, No. 5 (1911).

The potentials of the calcium salt mixtures also corroborate the results obtained with potassium salt mixtures. Thus with the formula

$$E_{\text{obs. } 25^\circ} = E_k + 0.0591 \log \frac{[\text{ferricy. ion}].[Ca^{++}]^z}{[\text{ferroc. ion}]} \quad (\text{III})$$

a fairly constant set of  $E_k$  values is obtainable. The values of  $E_k$  calculated, with various values of  $z$ , by means of the data and measurements of the mixtures of calcium salts are given in Table IV.  $E_k$  values obtained with  $z = 0.625$  have a mean value of  $E_k = 0.0916$  and a maximum difference between individual  $E_k$  values equal to 1.7 millivolts only.

The formula

$$E_{\text{obs. } 25^\circ} = E_k + 0.0591 \log \frac{[\text{Ca-ferricy.-U}].[Ca^{++}]^q}{[\text{Ca-ferroc.-U}]} \quad (\text{IV})$$

gives fairly constant  $E_k$  values with  $q = 0.575$ ; the mean  $E_k$  value is 0.1415 and the maximum difference between individual  $E_k$  values is 4.1 millivolts. Table IV shows the different values of  $E_k$  calculated by assigning different values to  $q$  in the potential Formula IV.

This completes the presentation of the results obtained directly from the experiments.

### Experimental Details and Calculations of Results.

**A. Preparation of Solutions and Determination of Conductivities.**—The details of the preparation of the different solutions and of the determinations of their conductivities are given under their respective headings in Notes 1 to 6 below, and the conductivity data are given in Table I.

*Note 1. Potassium chloride:* The values for the conductivities at  $25^\circ$  for this salt were taken from the tabulated results of Noyes and Falk<sup>1</sup> and are found in Table I. The salt which we used in our ferri-ferrocyanide mixtures was "C. P." stock recrystallized twice from conductivity water; the stock solutions were made up by carefully weighing out the required amount of the carefully dried salt and dissolving in conductivity water. The conductivity of our stock solution of potassium chloride was found to agree well with the data given by Noyes and Falk.

A Nernst conductivity vessel was used in all conductivity measurements; its capacity was determined with a freshly prepared 0.1 *N* potassium chloride solution, the specific conductance of which was taken as 0.01289 at  $25^\circ$ . The measurements were all made in a large water thermostat whose temperature remained constant at  $25^\circ$  to within  $0.1^\circ$ . Viscosity corrections were not applied to the results because we did not have accurate apparatus for this purpose.

*Note 2. Potassium ferrocyanide:* This salt was obtained pure by recrystallizing "C. P." stock twice from conductivity water. To avoid decomposition of the ferrocyanide by local overheating, hot saturated solutions were prepared by heating in a salt water bath. Stock solutions of known strength were made by accurately weighing out the carefully dried salt. Care was taken *not* to remove any of the water of crystallization of the ferrocyanide. In every case the strength of the stock solution was checked by means of titration with permanganate according to the method of de Haën.<sup>2</sup>

<sup>1</sup> THIS JOURNAL, 34, 454 (1912).

<sup>2</sup> Ann. Chem. Pharm., 90, 160 (1854).

The conductivities of these stock solutions of potassium ferrocyanide agreed well with previously published results.<sup>1</sup> The conductivity data for the higher concentrations of the potassium ferrocyanide as found in Table I were taken from measurements made in this laboratory.

*Note 3. Potassium ferricyanide:* This salt was prepared pure by recrystallizing "C. P." stock twice from conductivity water. The "standard" stock solutions were prepared by weighing out the carefully dried salts and checking the strength by reducing the ferricyanide in alkaline solution by means of ferrous sulfate to ferrocyanide, and then titrating with permanganate. The conductivities of the stock solutions prepared at various times were found to agree well with each other.

*Note 4. Calcium chloride:* The calcium chloride solutions were prepared by treating, in a calibrated volumetric flask, the required amounts of dry calcium carbonate (obtained by repeatedly washing freshly precipitated calcium carbonate) with the required amounts of hydrochloric acid of known strength. The solutions, after reaction, were boiled carefully to expel all carbon dioxide, and the solution diluted up to the mark with conductivity water. The strengths of these solutions were checked by means of the oxalate-permanganate titration and the silver chloride precipitation.

*Note 5. Calcium ferrocyanide:* This salt was prepared pure by recrystallizing "C. P." stock twice from conductivity water. The precaution for the prevention of local overheating as given in Note 2 was again observed. The salt was also prepared by treating the ether compound of hydroferrocyanic acid (in a flask with water) with an excess of purified calcium carbonate according to the method of Noyes and Johnston.<sup>2</sup> Solutions from both preparations of the salt gave the same conductivity. Stock solutions were prepared by weighing out the carefully dried salt, checking with the permanganate titration (here glacial acetic acid was used to acidify for the permanganate titration instead of sulfuric acid to avoid the formation of calcium sulfate).

*Note 6. Calcium ferricyanide:* This salt was prepared electrolytically from the purified calcium ferrocyanide. A concentrated solution of the purified calcium ferrocyanide was put into a clean porous cup and the cup placed in a glass jar containing a solution of purified potassium ferrocyanide. A platinum gauze anode and a mechanical stirrer extended into the porous cup. The cathode of platinum wire was placed into another porous cup filled with potassium ferricyanide solution in order to prevent the cathodic reduction product from reaching the anode cup. The current density employed was very low—not above 2 amperes per 100 sq. cm.—and the current was sent through the cell until a sample, tested with ferric chloride, gave no indication of ferrocyanide. The strength of the solution was determined by reducing the ferricyanide in alkaline solution by means of ferrous sulfate to ferrocyanide, and then titrating the latter with permanganate.

In order to obtain the conductivities at infinite dilution, two methods were used. In one, conductivities are plotted against concentrations and the curve extended until it cuts the conductivity axis: this point of intersection gives the conductivity at "zero" concentration. In the other—the method of Noyes and Coolidge<sup>3</sup>— $1/L$  is plotted against  $(CL)^{n-1}$ , and the value of  $n$  is taken so as to obtain a straight line: this line cuts the  $1/L$  axis at the value  $1/L_0$  ( $L_0$  being the equivalent conductivity at "zero" concentration). These two methods of determining

<sup>1</sup> THIS JOURNAL, 34, 454 (1912).

<sup>2</sup> *Ibid.*, 31, 987 (1909).

<sup>3</sup> *Pub. Carnegie Inst. Wash.*, No. 63 (1907).

$L_o$  agreed well for all the salts used in this investigation with the exception of calcium ferricyanide. For this salt, the value of  $L_o$  obtained by extending the conductivity-concentration curve until it cuts the conductivity axis is 156, while the nearest approach to this value obtainable with the second method of determining  $L_o$ —plotting  $1/L$  against  $(CL)^{n-1}$ —is 158.8. The value of  $n$  required to give this latter value of 158.8 is as high as 1.8; the value of  $n$  for potassium ferrocyanide, potassium ferricyanide, and calcium ferrocyanide which gave the *straight line*<sup>1</sup> were all the same,  $n = 1.65$ . Hence the value 156 for  $L_o$  was taken as the correct value in preference to the value 158.8.

The equivalent conductance of the ferrocyanide ion,  $L_{(\text{ferroc.})}$ , obtained from  $L_o$  of calcium ferrocyanide by subtracting the equivalent conductance of the calcium ion,  $L_{\text{Ca}}$ , from the  $L_o$  value—is 110.0, while  $L_{(\text{ferroc.})}$  obtained from the  $L_o$  of potassium ferrocyanide is 110.5— which figures agree well with each other.

The equivalent conductance of the ferricyanide ion at 25° was found to be 93.2 as determined from the potassium ferricyanide data and 96 as determined from the calcium ferricyanide data. In the calculations of the conductivities of the mixture, the value of the equivalent conductance of the ferricyanide ion was taken as 93.2, because with this value

<sup>1</sup> The  $n$  values for all these salts, determined by a method developed in this paper, are different from 1.65 and from each other; but they do not apply to solutions of very low concentrations and hence they cannot be used for extrapolation to zero concentration in order to determine the  $L_o$  values. The "straight line" extrapolation method for determining  $L_o$  was the only one available to us, and the use of  $n = 1.65$  in these  $L_o$  determinations has no connection with the use of other  $n$  values for higher concentrations.

<sup>2</sup> Repeated in this laboratory and found to agree with the data of Noyes and Falk.

<sup>3</sup> THIS JOURNAL, 34, 454 (1912).

<sup>4</sup> Concentration is 633 milliequivalents per liter.

the observed conductivities agreed fairly well with the calculated conductivities.

**B. Potential Measurements.**—The potential measurements of the different ferro-ferricyanide mixtures were made by means of an accurate potentiometer system, consisting of an extremely sensitive galvanometer of the D'Arsonval type, a Weston cell standardized by the Bureau of Standards at Washington, and a carefully prepared calomel electrode. This electrode was one of several which were found to remain constant to each other, and it was always kept in the thermostat, where all measurements were made. In the mixtures, gold electrodes are found to give more satisfactory results than platinum electrodes, which confirms the observations of Lewis<sup>1</sup> and of E. Mueller.<sup>2</sup> Since all mixtures were made up at a temperature slightly below the temperature of the bath, 25°, the

The potentials of the potassium ferro-ferricyanide mixtures did not assume a steady value after having attained the temperature of the bath: most mixtures gave potential measurements that oscillated through a range of several tenths of a millivolt. In general the oscillation amounted to about three- or four-tenths of a millivolt—a few as high as a millivolt—and different mixtures of the same composition gave practically always the same range of oscillation within the same limits. The measure-

ments\* were taken every ten minutes and the period of observation extended over two and one-half to three hours. The final potentials recorded in Tables II and III were an average of the entire series of measurements. Most mixtures were made up three times and few as many as four times. The calcium ferro-ferricyanide mixtures were extremely steady—at most, they showed much less oscillation than the potassium ferro-ferricyanide mixtures.

The numerical data and results of all this work have been presented in Tables I to IV.

### Theoretical Considerations.

(a) **Significant Values of  $n$  and  $k$  for Ferricyanides and Ferrocyanides.**—In attempting to determine the  $n$  and  $k$  values of salts, we must neglect the range of extremely small concentrations and confine our consideration to the larger concentrations, because different causes operate in the two concentration ranges to produce variations in the values of  $n$  and  $k$ . This may be seen readily from the ionization function of Kraus and Bray<sup>1</sup> for uni-univalent salts:

$$\frac{[A^+][B^-]}{[AB]} = K + k [\Sigma i]^{2-n}$$

With very small values of  $\Sigma i$ , the value of  $K$  forms a large part of the right side value, but with larger values of  $\Sigma i$ , the value of  $K$  is negligible beside the term  $k(\Sigma i)^{2-n}$ . For the latter concentration range, the Kraus-Bray equation reduces to the Storch equation

$$\frac{[A^+][B^-]}{[AB]} = k[\Sigma i]^{2-n}$$

It is evident that the application of the Storch equation to ranges of very small concentrations will require values of  $n$  which increase rapidly as  $\Sigma i$  decreases,<sup>2</sup> because this procedure amounts to neglecting the term  $K$  when its relative value is large enough to affect the result. It is evident that this cause of the  $n$  and  $k$  changes is essentially different from the cause or causes that bring about  $n$  and  $k$  changes in the ranges of higher concentrations.

If the causes of the changes in  $n$  and  $k$  which operate in the higher concentration ranges be assumed to continue *unimpaired* into very small concentration ranges, the values of  $n$  and  $k$  would tend toward certain final maximum values which we may obtain by extrapolation and which will be referred to in this paper as the  $n$  and  $k$  values at "zero concentration."

It should be noted that the formula

$$\frac{[C_i]^n}{[C_\infty]} = k,$$

<sup>1</sup> Kraus and Bray, *THIS JOURNAL*, 35, 1315 (1913).

<sup>2</sup> Bates, *Ibid.*, 35, 519 (1913).

shows that a lower value of either  $n$  or  $k$  will give a lower value for the other, even when all other quantities remain the same. Since the published values<sup>1</sup> of  $n$  for different concentration ranges correspond to different values of  $k$ , it is necessary to ascertain the nature of the change of *one* of these with concentration, while the other is kept *constant*. For this purpose, we have calculated from the data of Noyes and Falk the values of  $n$  for  $C = 200$  milliequivalents, with  $k$  from the concentration range 1-20, and have obtained the following results: the  $n$  values at  $C = 200$  thus obtained are *never greater* than those for lower concentrations, and for different salts, the "n-drops" vary considerably. Table V gives a number of values for illustration.

TABLE V.

Values of  $n$  with corresponding average values of  $k$  for certain concentration ranges;<sup>2</sup> and values of  $n$  for  $C = 200$  obtained with *maximum* value of  $k$  (from range 0.1-20) showing rate of change of  $n$  with  $\Sigma i$  (at 18°).

<sup>1</sup> THIS JOURNAL, 34, 480 (1912).

<sup>2</sup> Conductivity data from Noyes and Falk, THIS JOURNAL, 34, 454 (1912). Attention should be called to the fact that some of these  $n$  values are different from those calculated by Noyes and Falk. Our calculations were made by assuming various values for one and calculating the other with the formula  $(C_i)^n / (C_n) = k$ , and then choosing that pair of values which gave the least variation.

In order to determine the  $n$  and  $k$  for any one salt, we should take its equivalent conductivities at three slightly different concentrations, and determine the values of  $n$  which come nearest to giving straight lines—or, in other words, we should apply to them the well-known procedure of A. A. Noyes<sup>1</sup> for determining the equivalent conductivity at infinite dilution. The closer the three points are taken together, the more accurate will be the determination of  $n$  (and hence of  $k$ ); but for most salts, the changes in  $n$  and  $k$  with concentration are small enough to allow of drawing the straight line through points corresponding to a considerable range of concentrations as has been done by Noyes and Falk.<sup>2</sup>

But with ferricyanides and ferrocyanides, the  $n$  and  $k$  values vary so greatly<sup>3</sup> that the determination of the values of the latter would require the employment of three very slightly different concentrations. Instead of doing this, we made use of the following observation: it has been shown that when  $k$  is kept constant, the  $n$  values of all salts decrease with concentration; hence it follows that with  $n$  kept constant, the  $k$  values should *increase*. For those salts for which the “ $n$ -drops” (with constant  $k$ ) are small, these rises in  $k$  will be very small—and hence inappreciable over a *limited* concentration range—but for ferricyanides and ferrocyanides, the  $k$  rise should be large. Hence we calculated by means of the ionization data of our most dilute solutions of ferricyanides and ferrocyanides the  $k$  values obtained with different  $n$  values, according to the formula

$$\frac{C_i^n}{C_u} = k,$$

and then selected for each salt those  $n$  values for the “ $n$  values at zero concentration” which gave series of moderately, but plainly rising  $k$  values. The “limits” which these  $k$  values appear to approach as the concentrations approach zero were taken as the “ $k$  values at zero concentration.”

It should be realized that this relation between the changes in  $n$  and  $k$  values exists only with concentrations expressed in *whole* numbers. Since we have expressed concentrations in milliequivalents, the values used here are all greater than *one*.

In concluding this discussion of the  $n$  and  $k$  values, we present below the values for ferricyanides and ferrocyanides of the “ $n$ -drops” (with constant  $k$ ) corresponding to a  $\Sigma i$  range of 1 to 150 milliequivalents per liter. Attention should be called to the fact that all of these “ $n$ -drops” are

<sup>1</sup> *Pub. Carnegie Inst. Wash.*, 63, 50.

<sup>2</sup> *THIS JOURNAL*, 34, 480 (1912).

<sup>3</sup> It was on this account that Johnson (*THIS JOURNAL*, 31, 987 (1909)), could not obtain a straight line graph through a number of points representing a considerable concentration range.

TABLE VI.

Values of "k" for various values of "n" in the dilution formula  $\frac{[C_1]^n}{[C_2]} = k$ .

## (a)—Calcium Ferrocyanide:

Concentration.	n = 1.625.	n = 1.600.	n = 1.575.	n = 1.550.	n = 1.525.
5.0	0.998	0.983	0.965	0.946	0.932
10.0	1.102	1.069	1.038	1.008	0.977
10.0	1.232	1.171	1.121	1.072	0.922

The values obtained with the concentrations below 5.0 are irregular and hence have been omitted. The values obtained with  $n = 1.525$  show no progression with concentration; those obtained with  $n = 1.625$  show a great deal of progression; while the values obtained with  $n = 1.550$ ,  $n = 1.575$ , and  $n = 1.600$  show moderate amounts of progression, and hence these values of  $n$  have been accepted. The corresponding  $k$  values at zero concentration have been placed at 0.930, 0.945, and 0.960, respectively.

## (b)—Potassium Ferrocyanide:

Concentration.	n = 1.700.	n = 1.675.	n = 1.650.	n = 1.600.
2.0	9.430	9.335	9.130	8.920
5.0	10.180	9.850	9.510	8.910
10.0	11.000	10.340	9.950	9.030
20.0	12.320	11.520	10.800	9.520

The values obtained with the concentrations below 2.0 are irregular and are hence omitted. The values of  $n = 1.700$  show a great deal of progression; those for  $n = 1.600$  show no progression; while the values for  $n = 1.675$  and  $n = 1.650$  show a moderate amount of progression, and hence these  $n$  values have been accepted. The corresponding  $k$  value at zero concentration have been placed at:  $k = 9.0$  for  $n = 1.650$ ,  $k = 9.15$  for  $n = 1.675$ , and  $k = 9.30$  for  $n = 1.700$ .

## (c)—Calcium Ferricyanide:

Concentration.	n = 1.550.	n = 1.575.	n = 1.600.	n = 1.625.	n = 1.650.	n = 1.700.
2.0	3.34	3.36	3.40	3.43	3.46	3.52
5.0	3.52	3.63	3.74	3.85	3.97	4.21
10.0	3.49	3.58	3.80	3.01	4.08	4.52
20.0	4.06	4.31	4.56	4.85	5.16	5.87

The values obtained with the concentrations below 2.0 are irregular; the values for  $n = 1.550$  show little or no progression, while the values for  $n = 1.700$  show an excessive progression; hence the value  $n = 1.575$ ,  $n = 1.600$ ,  $n = 1.625$ , and  $n = 1.650$ , have been accepted. The corresponding  $k$  values at zero concentration have been placed at 3.30, 3.40, and 3.60, respectively.

## (d)—Potassium Ferricyanide:

Concentration.	n = 1.650.	n = 1.700.	n = 1.725.	n = 1.750.	n = 1.775.
2.0	23.18	23.96	23.35	24.70	25.10
5.0	22.05	23.75	24.63	25.53	26.60
10.0	21.75	24.25	25.62	27.00	28.45
20.0	24.15	27.65	29.10	31.90	34.20

The values obtained with the concentrations below 2.0 are irregular; the values for  $n = 1.650$  show no consistent progression, for  $n = 1.700$  not quite enough progression, while for  $n = 1.775$  the progression is excessive. The values  $n = 1.725$  and  $n = 1.750$  have been selected, and the corresponding  $k$  values at zero concentration have been placed at 22.0 and 23.0, respectively.

large, \*that the "*n*-drops" for the two potassium salts have the same value, and that those for the two calcium salts have the same value.

TABLE VII.

Rate of Change of *n* with  $\Sigma i$  and a Comparison of the (*n* - 1) Values with the Values of *x*, *y*, *z* and *q* for the Ferricyanides and Ferrocyanides of Potassium and Calcium.

Salt.	<i>k</i> value at "zero conc."	<i>n</i> value at "zero conc."	<i>n</i> values at approx. $\Sigma i = 150$ m. eq. per liter with <i>k</i> constant.	Change of <i>n</i> with change in $\Sigma i$ , 0.0—150.	<i>n</i> -1 values.	Values of <i>x</i> , <i>y</i> , <i>z</i> , and <i>q</i> .
$K_3Fe(CN)_6$ .....	22.00	1.725	C = 250 $\Sigma i = 156$	0.215	0.725	0.725
	23.00	1.750	1.510	0.233	0.750	0.750
			1.517			
$K_4Fe(CN)_6$ .....	9.00	1.650	C = 320 $\Sigma i = 149$	0.186	0.650	0.650
	9.15	1.675	1.464	0.205	0.675	0.675
	9.30	1.700	1.470	0.223	0.700	0.700
			1.473			
$Ca_3(Fe(CN)_6)_2$ .....	3.40	1.600	C = 400 $\Sigma i = 160$	0.280	0.600	0.600
	3.50	1.625	1.320	0.299	0.625	0.625
	3.60	1.650	1.326	0.320	0.650	0.650
			1.330			
$Ca_2Fe(CN)_6$ .....	0.93	1.575	C = 750 $\Sigma i = 151$	0.290	0.550	0.575
	0.94	1.600	1.260	0.310	0.575	0.600
	0.96	1.625	1.265	0.355	0.600	0.625
			1.270			

It is evident from the last two columns that

$x + 1 = n$  for potassium ferricyanide at "zero" concentration.

$y + 1 = n$  for potassium ferrocyanide at "zero" concentration.

$z + 1 = n$  for calcium ferricyanide at "zero" concentration.

$z + 1 = n$  for calcium ferrocyanide at "zero" concentration.

(b) **The Relation between the Activities and the Concentrations of the Ferricyanides and Ferrocyanides.**—For uni-univalent salts, it may be considered fairly well established<sup>1</sup> that the values of ( $2 - n$ ) are the sum of the exponents of the  $\Sigma i$  factors by which the concentrations must be multiplied or divided to obtain the activities. Thus, if  $[Tl].[Cl].[1/\Sigma i]^a$  is the product of the activities of the ions of thallous chloride, and  $[TlCl].[\Sigma i]^b$  is the activity of the un-ionized molecules, then

$$\frac{[Tl].[Cl]}{[TlCl]} = k[\Sigma i]^a + b = k[\Sigma i]^2 - n$$

If, as we assume throughout this paper, polyionic salts form no intermediate ions and that the conductivity ratio gives the percentage of salt ionized into the ordinary simple ions, then the fact that, even in mixtures<sup>2</sup> the conductivity function for polyionic salts is of the form

$$\frac{[A^{++}].[B^-]}{[AB]} = k[\Sigma i]^2 - n$$

instead of the form

<sup>1</sup> Bray, *THIS JOURNAL*, 33, 1673 (1911).

<sup>2</sup> Sherrill, *Ibid.*, 32, 741 (1910).

$$\frac{[A^{++}].[B^{-}]^2}{[AB]} = k[\Sigma i]^{3-n}.$$

This fact indicates that the relation between the concentrations and the activities of the components of polyvalent electrolytes (salts) includes another relation, different from the relation shown above for uni-univalent electrolytes, and which takes the place of—cancels—the higher powers otherwise required by the mass law. If this idea is correct, then the “cancelling” in the conductivity function for potassium ferrocyanide amounts to practically one  $[K^{+}]$  more than in the conductivity function for potassium ferricyanide. Furthermore, we have

$$\frac{[\text{ferricy. ion}].[K^{+}]^{0.750}}{[K\text{-ferricy.}-U]} = 2.3 = \frac{[\text{act. ferricy. ion}].[K^{+}]^3}{[\text{act. K-ferricy.}-U]}$$

and

$$\frac{[\text{ferrocy. ion}].[K^{+}]^{0.675}}{[K\text{-ferrocy.}-U]} = 9.15 = \frac{[\text{act. ferrocy. ion}].[K^{+}]^4}{[\text{act. K-ferrocy.}-U]}$$

Dividing *left*, *center*, and *right* of the first by the corresponding part of the last we obtain the following “concentration-activity relations from conductivities:”

$$\frac{\frac{[\text{ferricy. ion}]}{[K\text{-ferricy.}-U]}.[K^{+}]^{0.075}}{\frac{[\text{ferrocy. ion}]}{[K\text{-ferrocy.}-U]}} = 2.4 = \frac{\frac{[\text{act. ferricy. ion}]}{[\text{act. K-ferricy.}-U]}}{\frac{[\text{act. ferrocy. ion}]}{[\text{act. K-ferrocy.}-U]}. [\text{act. K}^{+}]}$$

Again, equating the expressions given by our *two* potential Formulas I and II for the potential for any particular ferri-ferrocyanide mixture, we obtain

$$E_{k_1} + 0.0591 \log \frac{[\text{ferricy. ion}].[K^{+}]^{0.750}}{[\text{ferrocy. ion}]} = E_{k_2} + 0.0591 \log \frac{[K\text{-ferricy.}-U].[K^{+}]^{0.675}}{[K\text{-ferrocy.}-U]}.$$

When numerical values are substituted for  $E_{k_1}$  (0.0526) and for  $E_{k_2}$  (0.0753), and this equation is simplified, it reduces to the *left-hand* equality in the concentration-activity relation above:

$$\frac{\frac{[\text{ferricy. ion}]}{[K\text{-ferricy.}-U]}.[K^{+}]^{0.075}}{[\text{ferrocy. ion}]} = 2.4$$

If we use activities in place of concentrations, we obtain

$$E_{k_1} + 0.0591 \log \frac{[\text{act. ferricy. ion}]}{[\text{act. ferrocy. ion}]} =$$

$$E_{h_2} + 0.0591 \log \frac{[\text{act. K-ferricy.-U}][\text{act. K}^+]}{[\text{act. K-ferrocy.-U}]},$$

and this reduces to the *right-hand* equality in the concentration-activity relation above. Hence these two equations give us the same "concentration-activity relations" as that obtained above from the conductivity functions.

This relation shows that for all values of  $\Sigma i$ —

$$x - y = n_i - n_o$$

because  $x$  and  $y$  are constant, and  $n_i$  and  $n_o$  decrease equally with  $\Sigma i$ . Since these four quantities are determined from *totally* independent data, this result shows that the "concentration-activity" relation of each component is the same in the conductivity functions as in the potential function.

It appears to us that the exponent of  $[\text{K}^+]$ —i. e.,  $x - y$  or 0.075—is the *sum* of the different powers of  $[\text{K}^+]$  which give the factors by which the different concentrations in the concentration must be multiplied to make them equal to the activities of the respective substances—as was illustrated with the thalious chloride at the beginning of this section. Seen in this light, the factor  $[\text{K}^+]^{0.750}$  under the logarithm in our potential Formula I

$$\frac{[\text{Ferricy. ion}].[\text{K}^+]^{0.750}}{[\text{ferrocy. ion}]}$$

has merely a numerical significance: it is the factor by which the concentration ratio

$$\frac{[\text{ferricy. ion}]}{[\text{ferrocy. ion}]}$$

must be multiplied to make it equal to the activity ratio

$$\frac{[\text{act. ferricy. ion}]}{[\text{act. ferrocy. ion}]},$$

and the factor  $[1/[\text{K}^+]^{0.325}]$  in our potential Formula II—

$$\frac{[\text{K-ferricy.-U}].[\text{K}^+]}{[\text{K-ferrocy.-U}]} \cdot \frac{[1]}{[\text{K}^+]^{0.325}}$$

serves the corresponding purpose. Evidently the activity of the ferrocyanide ion increases more with  $\Sigma i$  than that of the ferricyanide ion; while for the un-ionized molecules the reverse is true.

It is rather surprising that  $x$  and  $y$  are constant while the similar exponent  $n$  varies with  $\Sigma i$ . Perhaps the constancy of  $x$  is due to the chemical similarity between the ferricyanide ion and the ferrocyanide ion on account of which any "secondary" changes (with  $\Sigma i$ ) in the concentration-activity relation of one is undergone to an equal extent by the other; and since the ratio of these ions appears in the potential formula, such

secondary effects would "cancel" out. In the same way, the constancy of the other exponents  $y$ ,  $z$ , and  $q$  might be due to the chemical similarity of the other pairs of components concerned.

Finally, attention should be called to the fact that although

$$\frac{[\text{ferricy. ion}].[K^+]^{n-1}}{[K\text{-ferricy.-U}]} = k,$$

yet this relation cannot be used to substitute  $[K\text{-ferricy.-U}]$  for  $[\text{ferricy. ion}].[K^+]^z$ , because  $x$  is equal to the *maximum* value of  $n_i$  only, and not to the lower values of  $n_i$  corresponding to larger values of  $\Sigma i$ .

### Summary.

1. Conductivity measurements were made on solutions of potassium ferrocyanide and potassium ferricyanide, on solutions of mixtures of these and on mixtures of these with potassium chloride. The results were compared with results calculated by means of the rule of mixtures, and a fair degree of agreement was obtained.

2. Conductivity measurements were made on the corresponding calcium salts and on corresponding mixtures of these—with practically the same agreement between the observed and the calculated results.

3. The potentials of all these mixtures were measured against the "normal" calomel electrode.

4. The constituent ions and un-ionized molecules in all these mixtures were calculated on the assumption that intermediate ions are absent. The following empiric formulas were found to represent the dependence of the potentials upon the constituents of the mixtures through a  $K^+$  range of 10 to 400 milliequivalents per liter:

$$E_{\text{obs. } 25^\circ} = E_{h_1} + 0.0591 \log \frac{[\text{ferricy. ion}][K^+]^{0.75}}{[\text{ferrocy. ion}]}$$

and

$$E_{\text{obs. } 25^\circ} = E_{h_2} + 0.0591 \log \frac{[K\text{-ferricy.-U}][K^+]^{0.675}}{[K\text{-ferrocy.-U}]}$$

Corresponding formulas were found to hold for the calcium salts.

5. A new method was presented for deriving significant values of  $n$  and  $k$  for such salts as ferricyanides and ferrocyanides, for which these values vary greatly with the concentration. It was shown that the  $n$  values of the two potassium salts change equally with  $\Sigma i$ . The same is true for the calcium salts. It was found that the "maximum" values of  $n$  (i. e., the limits they approach with decreasing  $\Sigma i$ ) bear a simple numerical relation to the exponents of  $[K^+]$ —or of  $[Ca^{++}]$ —in the potential formulas above.

6. It was shown that certain of these observed relations are necessary consequences of the assumptions that the concentration-activity relation

of each component in the conductivity functions is the same as in the potential functions.

## THE BASIC COPPER SULFATES.

By S. W. YOUNG AND ALLEN EDWIN STEARN.<sup>1</sup>

Received July 24, 1916.

### Introductory.

In connection with some investigations on the genesis of copper ores, the problem of the formation and character of Brochantite or native basic copper sulfate comes under consideration. The analyses of this mineral give widely varying results, so divergent in fact as to indicate the probability that the substance is not of fixed composition. It was decided to attack the whole problem from the purely chemical side and the first results of the investigation are contained in this paper.

In looking over the literature on the basic copper sulfates one is struck at once by the large number of such compounds described. In the Gmelin-Kraut "Handbuch" some thirty-five are described as presumably definite compounds. These supposed compounds vary between the limits,  $10\text{CuO}\cdot\text{SO}_3$  and  $2\text{CuO}\cdot\text{SO}_3$ , with varying amounts of water. In some cases, salts, which differ from one another only in water content and this to only a very small degree, are given as distinct individuals. For example, one finds on record  $4\text{CuO}\cdot\text{SO}_3\cdot 3\text{H}_2\text{O}$  and  $4\text{CuO}\cdot\text{SO}_3\cdot 3\frac{1}{2}\text{H}_2\text{O}$ . Five different formulas are given for salts supposed to be identical with natural Brochantite, namely:  $4\text{CuO}\cdot\text{SO}_3\cdot 3\text{H}_2\text{O}$ ;  $7\text{CuO}\cdot 2\text{SO}_3\cdot 5\text{H}_2\text{O}$ ;  $7\text{CuO}\cdot 2\text{SO}_3\cdot 6\text{H}_2\text{O}$ ;  $3\text{CuO}\cdot\text{SO}_3\cdot 2\text{H}_2\text{O}$ ; and  $3\text{CuO}\cdot\text{SO}_3\cdot 3\text{H}_2\text{O}$ .

It seemed, on the face of it, to be highly improbable that such a large number of definite individuals of this class should exist, and good grounds for doubt are to be found by examination of the methods of preparation which have been used. Without going into detail concerning these methods, they may be fairly satisfactorily summarized under three heads:

1. Heating of copper sulfate solutions.
2. Precipitation from copper sulfate solutions by means of alkaline reagents such as sodium, potassium, calcium,<sup>2</sup> and ammonium hydroxides and carbonates, and in some cases by zinc oxide, as well as by acetates of the alkali metals.
3. Dilution of ammoniacal solutions of copper sulfate with water.

<sup>1</sup> Abstract of a thesis presented by Allen Edwin Stearn to the faculty of Stanford University, in partial fulfilment of the requirements of the degree of Master of Arts, May, 1916.

<sup>2</sup> Many salts are described by Pickering as a result of his studies of the Bordeaux mixture.

Of these methods, the second and third are open to the objections that foreign substances are present, and that the composition of the salt will naturally vary with the amount of precipitant used and presumably with the way in which it is added, whether slowly or rapidly. All three methods are open to the objection that, judging from the written accounts of the investigations, the products obtained do not represent equilibrium conditions. As will be shown in the experimental part of this paper, the reactions resulting in the formation of basic copper sulfates are extremely sluggish, requiring about three months at  $25^{\circ}$  for completion. It was with the purpose of adding something of clearness to the knowledge of these compounds that the following experiments were carried out. The general question which we set ourselves to answer is "are the basic sulfates of copper a set of compounds of definite composition, or are they a series of mixed crystals in variable proportions?"

### Experimental.

The method adopted for the production of the basic sulfates was the very simple one of allowing copper sulfate in solution in water, to combine with finely divided copper oxide. Preliminary experiments showed that this reaction was sufficiently rapid to be made use of. If copper oxide is allowed to stand at rest for three or four days in contact with a moderately strong solution of copper sulfate, it becomes thoroughly set into a hard cake of greenish gray, owing to the formation of basic salt. This cake is very hard and very difficultly soluble even in strong acids and ammonia.

Provision was made for three sets of duplicate samples, one to be run at  $25^{\circ}$ , one at  $37.5^{\circ}$  and one at  $50^{\circ}$ . In each set were six samples. These were placed in six magnesium citrate bottles, and the samples were made up as follows: In each bottle was placed 150 cc. of a solution of copper sulfate containing 0.04394 g. of copper in 1 cc. To the bottles were added amounts of copper oxide corresponding, respectively, to  $\frac{1}{4}$ ,  $\frac{1}{2}$ , 1, 2, 4 and 8 molecules for each molecule of copper sulfate. In addition to the six bottles in each set, a seventh was prepared containing one molecule of copper oxide to one of sulfate. These three extra bottles were designed to serve as check bottles from which samples might be taken from time to time in order to determine the progress and completion of the reaction. The three sets were then placed in thermostats which could be maintained to within  $0.1^{\circ}$  of the above mentioned temperatures, and were rotated continuously until equilibrium was established, as shown by samples taken from the check bottles. When the copper content of the samples of filtrate taken from the check bottles failed to show any further decrease during one week, it was considered that equilibrium had been attained. The time required for reaching equilibrium at the different temperatures is approximately shown in the following table:

Temperature.	Days required for equilibrium.
25.0°	88
37.5°	22
50.0°	15

These figures show how unreliable must be the conclusions of previous investigators, who have allowed only a few minutes, or at most a few hours (often at room temperature) for the preparation of their salts.

The treatment of the products obtained in the above manner was as follows: The bottles were taken from the thermostat one by one and the contents thrown on a rapid suction filter. As soon as filtration was complete, the solids were placed in specially prepared containers and centrifuged at high speed for an hour, after which they were air dried between watch glasses. Both filtrate and solids were preserved for analysis.

The filtrates were analyzed for copper by the electrolytic method. Through an inadvertence, they were not analyzed for sulfuric acid, as should have been done, in order to check certain conclusions based on the results of analysis of the solids. Table I gives the results of the copper determinations for all the filtrates.

TABLE I.

Amount of copper remaining in 5 cc. of the solutions. In column headed CuO are given the number of molecules of copper oxide added for each molecule of copper sulfate in the original mixtures.

CuO.	25°	37.5°.	50°.
$\frac{1}{4}$	0.1916	0.1956	0.1937
$\frac{1}{2}$	0.1606	0.1661	0.1657
1	0.1099 (0.1153)	0.1094	0.1094
2	0.0028 (0.0369)	0.0022	0.0018
4	0.0008	0.0008	0.0006
8	0.0006	0.0007	0.0002

The initial concentration was 0.2197 g. copper in 5 cc. From the table it is clear that in cases where two molecules of oxide to one of sulfate had been used the removal of copper from the solution was very nearly complete and in cases where more than this quantity of the oxide was used, the removal was always virtually complete. It is also evident that the amount of copper left in the solution is practically independent of the temperature.

In the 25° column there will be noticed two values in parentheses. These were the results obtained in the regular run of the samples. As they were markedly higher than was to be expected from the neighboring results, it was suspected that there might possibly have been formed in these cases a metastable form of higher solubility. Two new bottles were, therefore, prepared in exactly the same way as the others, except that they were seeded with a small amount of salt from some of the bottles that showed normal conduct. These were rotated for ninety days and gave the results used in the 25° column, which are in good agreement with neighboring results.

An examination of the solids obtained in the above experiments showed them to be of two sorts. Those prepared by using the smaller amounts of oxide, up to two molecules to one of sulfate, were clear light grayish green. Those containing larger amounts of oxide were darker in color and showed a tendency toward stratified settlement. This was taken as an indication of an excess of uncombined copper oxide, a conclusion which received confirmation upon a microscopic examination which showed the light green crystals of basic salt and black particles of oxide side by side. The examinations failed to yield any evidence of crystals of basic salt of more than one sort. The crystals were very minute and the evidence of the microscopic examination is of itself perhaps of but little importance, but offers some support to conclusions to be drawn later from the results of analysis.

All samples of the salts obtained, except those which showed free copper oxide, were analyzed for copper, sulfur trioxide and water. It was found that by heating to  $700^{\circ}$  for 15 hours in an electric furnace, all water and  $\text{SO}_3$  were driven off, leaving pure copper oxide showing no traces of  $\text{SO}_3$ .  $\text{SO}_3$  was determined from another sample, by dissolving in hydrochloric acid and precipitating with barium chloride. Water was determined by the difference between this result and that obtained by ignition. Copper was also determined in several samples by electrolysis and gave good checks with the values obtained by ignition. It was found to be impracticable to drive off water without also driving off some  $\text{SO}_3$ , so that direct determinations of water were not made.

In Table II there is given a summary of the analyses, averages only being given. They are the averages of at least two (and often more) determinations in every case.

### Discussion of the Results.

The first fact of importance to be noted is the negligible effect of temperature on the composition of the salts formed under otherwise like conditions. So closely do the analyses of the salts produced at the three temperatures check with one another, that it is safe to conclude that within the limits investigated the composition of the salts is independent of the temperature.

In the second place, it is to be noted that the amount of copper oxide in the salt increases with the amount added, as is to be expected. The amount of copper oxide which can be assimilated by one molecule of copper sulfate seems to be limited to about two molecules. The evidence furnished by the experiments is not sufficient to fix this limit beyond doubt, since the next higher amount of copper oxide used was four molecules to one of copper sulfate. Since, however, the salts produced in these cases contained large admixtures of unattacked copper oxide, and since the copper sulfate in the solutions was practically reduced to zero in all cases where two molecules of copper oxide to one of copper sulfate were used, and not where less than this amount was used, the presumption is very strong that this amount represents very closely the limit assimilable under the conditions of these experiments.

Another conspicuous fact shown by the results in Table III is that in all cases as the amount of copper oxide increases the amount of water decreases, and that as a limit the molecules of oxide and water to one of sulfate approach equality in the most basic salt, at the approximate value of two. In so far as is deducible from the evidence obtained in this investigation, the most basic salt which could be prepared by the method used would have approximately the formula  $\text{CuSO}_4 \cdot 2\text{CuO} \cdot 2\text{H}_2\text{O}$ . Whether there is a lower limit to the amount of copper oxide which may

be contained in a basic salt is not determinable from the evidence in hand, and remains a subject for further investigation.

In the literature, reference is made to several supposed salts which contain higher percentages of copper oxide than any that we have succeeded in obtaining. These salts were, however, invariably obtained by precipitations with alkaline reagents and the presumption is very strong that they were mixtures containing excess of hydroxide.

It is a well-known fact that ordinary solutions of copper sulfate are in general supersaturated with respect to basic sulfate, even though unsaturated with the normal sulfate. This is evidenced by the fact that prolonged standing or short boiling of such solutions results in the deposition of certain amounts of basic sulfates. It has been maintained that such basic sulfates show a definite composition, irrespective of the strength of the solutions from which they are prepared.<sup>1</sup> This point of view is maintained by Pickering in spite of serious lack of agreement in the results of his analyses. In order to convince ourselves upon this point the following experiments were carried out: Three bottles containing copper sulfate solutions of different strengths were prepared. The first contained a solution saturated at 80° diluted with five volumes of water; the second contained a solution which was saturated at 80° plus a considerable additional quantity of small crystals of copper sulfate, while the third contained solution saturated at 80° without any addition whatever. These bottles were placed in an electric oven and kept at 100° for a week, during which time they were frequently shaken. They were then removed, the contents quickly filtered and the basic sulfates (they are extremely insoluble) washed with water to remove excess of copper sulfate. These salts were dried and analyzed for copper. The results are given in Table IV.

TABLE IV.

Solution.	% CuO.
Sat. at 80° and diluted with 5 vols. water.....	66.34
Sat. at 80°.....	67.00
Sat. at 80° with $\approx$ $\text{CuSO}_4$ crystals.....	68.21

As is readily seen the composition of the basic sulfates prepared in this way is highly influenced by the concentration of the solutions from which they are prepared.

### Summary.

1. A considerable number of basic sulfates of copper were prepared by the direct action of copper oxide on solutions of copper sulfate, at three different temperatures.

2. The time required for such systems to attain equilibrium is about three months at 25° and about two weeks at 50°.

<sup>1</sup> Cf. Pickering, *Chem. News*, 47, 181.

3. Other conditions being constant, the composition of these basic sulfates is independent of the temperature of preparation within the range investigated.

4. The evidence obtained by a study of these salts makes it seem highly probable that they are not definite compounds, but rather are to be regarded as a three-component system in which all three components,  $\text{CuSO}_4$ ,  $\text{CuO}$  and  $\text{H}_2\text{O}$  (or if one prefers  $\text{CuO}$ ,  $\text{SO}_3$ ,  $\text{H}_2\text{O}$ ) are continuously variable within certain limits.

5. The evidence indicates that the maximum number of molecules of copper oxide that are capable of being taken up by one of copper sulfate is two, and that the formula for the most basic salt is probably quite close to  $\text{CuSO}_4 \cdot 2\text{CuO} \cdot 2\text{H}_2\text{O}$ .<sup>1</sup>

6. In salts of lower basicity the water content of the salt increases as the copper oxide content decreases, but there is as yet no evidence to show whether these changes continue throughout the whole range to normal  $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ .

7. Basic copper sulfates prepared by heating copper sulfate and water together in varying relative amounts does not lead to the formation of definite compounds as has been maintained.

8. There is some evidence indicating the formation, under undetermined conditions, of a metastable series of basic sulfates.

9. In view of the above facts, it is only natural that the mineral Brochantite, should show a variable composition, depending on the conditions of its formation.

## CHLORIDES IN PRESENCE OF THIOCYANATES.

By F. W. BRUCKMILLER.

Received July 20, 1916.

Rosanoff and Hill<sup>2</sup> have shown that chlorides can be determined in the presence of thiocyanates by means of Volhard's method after the latter have been decomposed by concentrated nitric acid. This paper intends to show that chlorides can also be titrated with silver nitrate and chromate

<sup>1</sup> Professor W. A. Noyes has kindly called the authors' attention to the fact that this formula corresponds to that of the normal copper salt of orthosulfuric acid,  $\text{S}(\text{OH})_2$ , with two molecules of water of crystallization, and may be written

<sup>2</sup> THIS JOURNAL, 29, 1467 (1907).

indicator after the thiocyanates have been decomposed with nitric acid. Such a method is useful in water analysis where chlorides and thiocyanates occur together and it is desired to know only the chlorine content.

The solution containing the chlorides and thiocyanates is heated to boiling and concentrated nitric acid added drop by drop, the amount depending upon the thiocyanate present. If present in large quantities, nitric acid is added until the solution turns a light brown. For small quantities 2-3 cc. of nitric acid are sufficient. The solution is boiled for 15 minutes and filtered if necessary (free sulfur being precipitated if the concentration of thiocyanate is large) and after cooling is neutralized with normal  $\text{NaHCO}_3$ , using methyl orange as indicator. A little more than enough for neutralization is added, and after adding 1 cc. of chromate indicator, silver nitrate is added to the usual end point.

The method assumes (1) that the thiocyanate may be decomposed at  $100^\circ$  by such quantities of  $\text{HNO}_3$  as are insufficient to oxidize the chloride or cause volatilization of  $\text{HCl}$ ; (2) that all but traces of hydrocyanic acid formed during decomposition can be volatilized during the time required for oxidation; (3) that the sulfur is not present in such a form as to react with the  $\text{AgNO}_3$ ; (4) that the color of the methyl orange indicator does not interfere with the chromate end point.

Rosanoff has shown that no chlorine is lost as such, or as hydrochloric acid, in boiling the solution with nitric acid, and we have been able to confirm his conclusions. Varying amounts of sodium chloride were taken and boiled with varying quantities of nitric acid, and the solutions analyzed for chlorine before and after. The results in Table I show that no chlorine was lost during the operation.

TABLE I.—EFFECT OF NITRIC ACID ON SODIUM CHLORIDE SOLUTION AT  $100^\circ$ .

In the decomposition of thiocyanate, hydrocyanic acid is one of the principal decomposition products. In pure solutions it is all removed by boiling, but in presence of chlorides a small quantity is always retained. In no case, however, was this amount larger than 3 mg. of CN per liter. This is not in accord with the work of Richards and Singer,<sup>1</sup> who find that larger quantities are retained. The complete removal

<sup>1</sup> *Am. Chem. J.*, 27, 208 (1902).

of the hydrocyanic acid is desirable, but traces do not interfere with the accuracy of the method. Even if 3 mg. per liter were always retained, the error in titrating chlorides in water analysis would be only 3 parts per million.

During decomposition the sulfur does not form any compound which in any way interfere with the titration with silver nitrate. No hydrogen sulfide was ever detected. Free sulfur forms if the concentration of thiocyanate is large. The exact products resulting were not determined, but, besides free sulfur, they are probably sulfate and complex organic compounds.

The presence of methyl orange in the solution gives a little different shade to the end point with chromate indicator but it is as easily duplicated and detected as is the color obtained in absence of methyl orange. Solutions of sodium chloride were titrated in presence and in the absence of methyl orange with the following results:

AgNO <sub>3</sub> with methyl orange (cc.).....	15.05	20.00	50.10	100.20
AgNO <sub>3</sub> without methyl orange (cc.)...	15.00	19.98	50.00	100.12

The solution is neutralized with sodium bicarbonate, instead of sodium hydroxide, to guard against an excess of hydroxyl ion in the solution with which silver nitrate reacts. An end point with the chromate indicator is obtained in a slightly acid solution but if considerable acid is present no end point is obtainable. The maximum concentration of (H<sup>+</sup>) allowable was determined and the results included in Table II.

To several solutions containing known quantities of chloride were added varying concentrations of sulfuric acid, beginning with 0.0004 N. Fifty cc. of each of these were titrated for chlorides according to the usual procedure.

TABLE II.—EFFECT OF ACID ON TITRATION OF CHLORIDES.  
Grams of Chlorine per Liter.

Conc. of H <sub>2</sub> SO <sub>4</sub> mols.	Present.	Found.	Present.	Found.	Present.	Found.	Present.	Found.
0.0002	0.026	0.026	0.084	0.084	0.104	0.104	0.206	0.206
0.0060	0.026	0.026	0.084	0.084	0.104	0.104	0.206	0.206
0.0010	0.026	0.026	0.084	0.084	0.104	0.104	0.206	0.206
0.0012	0.026	0.026	0.084	0.084	0.104	0.104	0.206	0.206
0.0014	0.026	0.026	0.084	0.084	0.104	0.104	0.206	0.206
0.0016	0.026	<sup>1</sup>	0.084	<sup>1</sup>	0.104	<sup>1</sup>	0.206	<sup>1</sup>

These results indicate that chlorides can be determined by titration in a 0.0014 M solution of sulfuric acid or a concentration of 0.0028 (H<sup>+</sup>), assuming that all of the acid is dissociated.

From these results we conclude that by decomposing the thiocyanates with hot nitric acid, chlorides can be determined volumetrically, using silver nitrate and chromate indicator.

**THE CATALYTIC DECOMPOSITION OF HYDROGEN PEROXIDE  
IN CERTAIN NONAQUEOUS SOLUTIONS.**

BY JAMES H. WALTON AND DEWITT O. JONES.

Received July 27, 1916.

The fact that aqueous solutions of hydrogen peroxide are extremely sensitive to the presence of foreign substances was recognized by Thenard,<sup>1</sup> who reached the conclusion that all substances exert some effect on this substance, some, like the acids, increasing its stability, others, like the finely divided metals and certain metallic oxides, tending to decompose it.

Concerning the stability of nonaqueous solutions of hydrogen peroxide towards foreign substances comparatively little is known. The metallic oxides, such as manganese dioxide and lead dioxide readily decompose ethereal solutions of the peroxide. To the knowledge of the authors, however, no data exist showing whether such soluble salts as the alkali iodides, which readily decompose hydrogen peroxide,<sup>2</sup> will show a similar action towards nonaqueous solutions of this substance.

**Experimental.**

In a series of experiments carried out by A. Brann,<sup>3</sup> it was found that ethereal solutions of the peroxide show absolutely no reaction when the following organic acids are dissolved in them: malic, picric, sulfanilic, citric, anthranilic, cinnamic, salicylic, gallic, camphoric, succinic, anisic, pyrogalllic, benzoic, oxalic, mono- and trichloroacetic, and stearic. The following are also without influence: acetamide, acetanilide, diphenyl amine, alloxan, *p*-toluidine, phenyl hydrazine, aniline, urethane, naphthalene,  $\beta$ -naphthylamine, nickel bromide, and the cobalt, calcium and cadmium salts of abietic acid. The following salts are soluble in ether, but they are decomposed when added to an ethereal solution of hydrogen peroxide, the decomposition being accompanied with the formation of a precipitate: cadmium iodide, ferric chloride, cupric chloride, copper oleate, and the abietates of silver, nickel, copper and manganese. The only ether soluble substance found that decomposed the ethereal solution of the peroxide catalytically, and without forming a precipitate, is lithium iodide. In this case the evolution of oxygen is copious.

Inasmuch as hydrogen peroxide is soluble in many other organic solvents,<sup>4</sup> and since many of these solvents dissolve some of the inorganic salts very readily, it was of interest to compare the activity of certain salts in nonaqueous and aqueous solutions of hydrogen peroxide. The following solvents were used: amyl acetate, amyl alcohol, isobutyl alcohol, and

<sup>1</sup> *Ann. chim. phys.*, **9**, 314 (1818).<sup>2</sup> Walton, *Z. physik. Chem.*, **47**, 2 (1904).<sup>3</sup> Dissertation, Wisconsin, 1914.<sup>4</sup> Walton and Lewis, *THIS JOURNAL*, **38**, 633 (1916).

quinoline. By shaking with the proper amounts of "perhydrol," solutions of the above were obtained, having concentrations of hydrogen peroxide varying from 1 to 3%. They also contained, of course, a small amount of water. In making an experiment, from 0.05 to 0.1 g. of the substance to be tested was dissolved in 5 cc. of the pure solvent. This was then added to the peroxide solution. If no gas was evolved the solution was carefully warmed. Table I gives the salts used and their behavior in the different solutions.

The experiments show that in general those substances that act as catalyzers to hydrogen peroxide in aqueous solution are similarly active when the peroxide is dissolved in nonaqueous solvents.

The great solubility of hydrogen peroxide in quinoline is evidenced by

the fact that at  $0^{\circ}$  for certain concentrations the partition coefficient<sup>1</sup>  $\frac{\text{H}_2\text{O}_2 \text{ in water}}{\text{H}_2\text{O}_2 \text{ in quinoline}}$  may be as low as 0.276.

An investigation of the rate of decomposition of a peroxide solution in quinoline was undertaken. Manganese acetate was used as a catalyzer. To find out whether or not the catalytic decomposition of hydrogen peroxide in quinoline solution is quantitative, a solution of peroxide in quinoline was prepared and two 25 cc. portions placed in flasks. To one flask manganese acetate dissolved in quinoline was added, to the other an aqueous solution of potassium iodide and the solutions allowed to stand until no further decomposition took place. The volumes of oxygen liberated in each case were the same, 42.7 cc.

Proof that the amount of oxygen does not vary to any great extent with the amount of catalyzer is shown by the following data, the experiments being carried out in a manner similar to those just described:

Gram of manganese acetate per 26 cc. of solution.....	0.1	0.1	0.05	0.05
Oxygen evolved at $0^{\circ}$ and 760 mm.....	34.80	34.75	35.00	34.70

A series of measurements of the velocity of decomposition of hydrogen peroxide in quinoline solution at  $25^{\circ}$ , using manganese acetate as a catalyzer was carried out.

### Reagents.

**Quinoline.** The synthetic product was used. This was redistilled, the portion coming over between  $234^{\circ}$  and  $236^{\circ}$  being employed in the experiments.

**Manganese acetate.** The purest preparation of a standard make was used. It contains one molecule of water of crystallization.

The hydrogen peroxide was Merck's "Perhydrol."

The quinoline-peroxide solution was prepared by dissolving 6 cc. of 15% hydrogen peroxide in 250 cc. of the quinoline. This gave a solution that contains about 2.5% of water.

### Procedure.

In carrying out an experiment 25 cc. of this solution were placed in a flask (Fig. 1) and 1 cc. of a quinoline solution of manganese acetate placed in the capsule A. The reaction flask was then put in a thermostat kept at  $25^{\circ}$ ; it was connected with a gas buret and its contents allowed to come to the temperature of the bath. By turning the rod B, the capsule was dropped into the quinoline solution. The flask was then shaken, and

Fig. 1.

<sup>1</sup> Walton and Lewis, *loc. cit.*

the velocity of the decomposition of the peroxide determined by reading the volumes of oxygen in the gas burets. A number of pieces of glass rod, C, placed in the flask, increased the efficiency of the shaking apparatus.

In the following tables,  $t$  = time in minutes;  $x$  = vol. dry oxygen evolved at  $0^\circ$  and 760 mm.; A = total vol. oxygen evolved; C = g. catalyst in 26 cc. of solution;  $K_1$  = velocity constant for a monomolecular reaction;  $K_2$  = velocity constant for a bimolecular reaction.

Average  $K_1$  = 0.0685

The constants in Table II show clearly that under the conditions of the experiment the hydrogen peroxide decomposes according to the second order of reaction, and not according to the first order, as in aqueous solutions of this concentration.

This may also be shown as follows: Let  $C_1, C_2, C_3$ , represent solutions of hydrogen peroxide of different concentrations, and  $\theta_1, \theta_2, \theta_3$ , the time necessary for decomposing 50% of these solutions, respectively.

For a monomolecular reaction  $\theta_1 = \theta_2 = \theta_3$ , for a bimolecular reaction  $\theta_1, \theta_2, \theta_3$ , vary inversely as the concentration, that is

$$\theta.C = \text{const.} = k.$$

In the following table, concentrations and corresponding values of  $\theta$  both expressed as cubic centimeters of oxygen evolved, are given:

C.....	41.2	30.9	20.6
$\theta$ .....	11.6	15.5	22.3
$\theta.C$ .....	478.0	479.0	459.0

The constancy of the value  $\theta.C$  is a further proof that this reaction is bimolecular.

A repetition of this experiment gave a value of  $K_2$  = 0.001968, as against 0.001814 for the results given in Table II. The experiment was repeated, using a freshly prepared solution of peroxide in quinoline. The value of  $K_2$  this time was 0.001546. It was suspected that this difference might be due to different amounts of water in the quinoline, caused by different

conditions of pressure, etc., when purifying this substance. To eliminate this variable the quinoline was saturated with water at 25°, and the water-saturated quinoline used in all subsequent experiments.

The experiment just described was repeated, the conditions being identical with the exception that water-saturated quinoline was used. The results are recorded in Table III.

An inspection of the values computed for  $K_1$  and  $K_2$  shows that the reaction is now monomolecular. Apart from the constancy of their constants this is shown by the fact that the time necessary to decompose 50% of a quinoline-peroxide solution is independent of the concentration of the peroxide. This is shown by the following data:

C.....	35	30	20	15
$\theta$ .....	10	10	10.2	10.2
$\theta.C$ .....	350	300	204	153

The change from a bi- to a monomolecular reaction is of interest, and brings to mind\* the investigations of Dyer and Dale<sup>1</sup> and Bassett,<sup>2</sup> who showed that when hydrogen peroxide solutions of a greater concentration than 1/9 mol per liter are decomposed by colloidal platinum the reaction is bimolecular, whereas in dilute solutions it decomposes according to the first order. In this investigation there is, however, no change of concentration. The change of the reaction from a bi- to a monomolecular reaction is obviously brought about by saturating the quinoline with water.

Experiments similar to those described were carried out with different amounts of catalyzer. The following results were obtained:

	(1)	(2)	(3)	(4)	(5)	(6)
Gram manganese acetate per						
26 cc. of solution....	0.005	0.005	0.0025	0.0025	0.00125	0.00125
Time required to decompose						
50% of the $H_2O_2$ (minutes).	10.2	10.1	22.9	22.1	109.5	121.5

Decreasing the concentration of the catalyzer by 50% approximately decreases the speed of the reaction by the same amount. When the concentration is further decreased, however, the reaction is much slower, as is shown by comparison of Experiments 3 and 4 with 5 and 6. This is due primarily to a side reaction, in which some of the hydrogen peroxide is used up in oxidizing the quinoline. A quinoline-hydrogen peroxide solution can be kept for several days without any appreciable change. Addition of enough catalyzer to decompose the peroxide in a few minutes yields practically all the oxygen; if a small amount of catalyzer is added however, so that the experiment runs for two or three hours, only a part of the oxygen (about 75%) will be evolved; the rest is used up in oxidizing the quinoline. The manganese acetate not only catalyzes the peroxide

<sup>1</sup> *Proc. Chem. Soc.*, 29, 55 (1913).

<sup>2</sup> *Ibid.*, 29-30, 56 (1913).

decomposition, but it also catalyzes the oxidation of the quinoline by the peroxide.

In order to study the relation between the conductivity and the effect of the different concentrations of catalyzer, conductivity measurements were made at 25° with quinoline saturated with conductivity water at 25°, then with manganese acetate dissolved in 26 cc. portions of the solution in the concentrations in which it was used as a catalyzer in the experiments described. The results obtained are tabulated below:

Gram of manganese ace-

tate per 26 cc.....	0.00	0.00125	0.0025	0.005
Specific conductivity....	$2.3 \times 10^{-6}$	$3.4 \times 10^{-6}$	$3.75 \times 10^{-6}$	$5.2 \times 10^{-6}$

From these data it is evident that there is no simple relation between the conductivity of the solutions of manganese acetate in water-saturated quinoline and the velocity with which the peroxide solutions are decomposed in the presence of the corresponding amounts of manganese acetate.

#### Summary.

The results of this investigation may be briefly summarized as follows:

1. A number of compounds that decompose aqueous solutions of hydrogen peroxide catalytically are also active as catalyzers towards solutions of hydrogen peroxide in amyl alcohol, amyl acetate, isobutyl alcohol and quinoline.

2. Hydrogen peroxide in quinoline solution is decomposed quantitatively by manganese acetate. If the manganese acetate is present in so small a concentration that the reaction is slow, a side reaction, *viz.*, the oxidation of the quinoline by the hydrogen peroxide, is also appreciably catalyzed by the manganese acetate.

3. A solution of hydrogen peroxide in quinoline containing about 2% of water, when decomposed catalytically by manganese acetate, follows the second order of reaction. If the quinoline is saturated with water the reaction is monomolecular.

4. In solutions containing the catalyzer in high concentrations the velocity of reaction is approximately doubled by doubling the concentration of the catalyzer.

### [CONTRIBUTION FROM THE SCHOOL OF CHEMISTRY, UNIVERSITY OF PITTSBURGH.] STUDIES IN DIALYSIS. I. THE DIALYSIS OF A COLLOIDAL SOLUTION OF HYDROUS CHROMIC OXIDE IN CHROMIC CHLORIDE.<sup>1</sup>

By MARKS NEIDLE AND JACOB BARAB.

Received July 14, 1916.

In an effort to prepare the red form of colloidal chromic oxide<sup>2</sup> by pass-

<sup>1</sup> Presented at the Spring Meeting of the American Chemical Society, 1916.

<sup>2</sup> Woudstra, *Z. Chem. Ind. Kolloide*, **5**, 33 (1909).

ing steam through a chromic acetate solution and dialyzing with intermittent changing of the diffusate, it was found that the chromium continued to diffuse until none was left in the membrane. Analysis of the diffusate from a solution of hydrous chromic oxide in chromic chloride showed a ratio of chromium to chlorine considerably greater than for pure chromic chloride. Colloidal solutions of hydrous ferric oxide in ferric chloride<sup>1</sup> do not behave in this way. At the end of twenty-four hours the ratio of iron to chlorine is 56 : 137 or less than Fe : 3Cl; it diminishes very rapidly until the amount of iron which diffuses can no longer be detected.

With very few exceptions, the process of dialysis has been employed simply to obtain a colloidal solution as free from electrolytes as possible. The observation that, in the dialysis of colloidal solutions of hydrous chromic oxide, the chromium diffuses more rapidly than the chlorine, suggested that a quantitative study of the dialysis of such solutions might throw some light on the nature of colloidal solutions and also on the process of dialysis.

#### Preparation of Solution of Hydrous Chromic Oxide in Chromic Chloride.

—Analysis of a commercial "C. P." preparation<sup>2</sup> of chromic chloride in the form of a gluey mass, gave the following results: chromium, 100 equivalents ( $\frac{1}{3}$  Cr); chlorine, 90 equivalents (1 Cl); sulfate, 3.3 equivalents ( $\frac{1}{2}$  SO<sub>4</sub>). The sulfate was removed by precipitation with the calculated amount of barium chloride added to a boiling solution of the chromic chloride. The filtrate was greatly diluted, heated to boiling and treated with ammonium hydroxide. Boiling was continued until the odor of ammonia became very faint. The hydrous chromic oxide was allowed to settle, washed three times by decantation, and finally filtered on a Büchner funnel. The desired amount of this hydrous chromic oxide, which now gave no tests for sulfate, was dissolved in small portions in the calculated amount of boiling 6 *N* hydrochloric acid. To bring the last portions into solution it was necessary to evaporate the solution to a small bulk. The resulting colloidal solution was filtered, diluted to a convenient volume, and kept as a stock solution. Its composition was: chromium, 0.1610 gram-equivalents ( $\frac{1}{3}$  Cr); chlorine, 0.0786 gram-equivalents (1 Cl) per 100 cc.

**Continuous Dialysis.**—One hundred cubic centimeters of the colloidal solution were placed in a parchment paper membrane, set up as shown in the diagram, and adjusted so that the levels of liquid, inside and outside,

<sup>1</sup> Picton and Linder, *J. Chem. Soc.*, 87, 1908 (1905).

<sup>2</sup> As an instance of the reliability of the analysis on the labels of C. P. chemicals, the label on this preparation reads: CrCl<sub>3</sub> + ?H<sub>2</sub>O. H<sub>2</sub>S metals,..... "nil." Fe,..... 0.0023%. S,..... present. K,..... present.

were the same. By means of stopcock C the flow of distilled water was regulated to a rate of about 800 cc. per hour. At intervals the vessel F was removed and replaced by another. The volumes of the diffusates were measured and convenient portions taken for analysis. The results expressed in terms of milliequivalents are given in Columns 4 and 5, Table I.

Fig. 1.

**Intermittent Dialysis.**—One hundred cubic centimeters of the stock solution were introduced into a parchment paper dialyser and suspended in a two-liter beaker containing 400 cc. of distilled water. The levels of the liquids on both sides of the membrane were practically the same initially. At the intervals given in Col. 3, Table II, the outer vessel was removed and another beaker containing 400 cc. of distilled water was placed in its stead.

**Dialysis without Changing Diffusate.**—Fifty cubic centimeters of the stock solution were placed in a parchment paper membrane and suspended in a liter beaker containing 400 cc. of distilled water. The dialysis was not disturbed except for the removal of samples from inside the membrane and from the diffusate for analysis. As no precaution was taken to prevent evaporation from the diffusate, its concentration is higher than it would have been if this precaution had been taken.

Each membrane was tested for leaks, at the conclusion as well as at the beginning of the experiment, by introducing colloidal hydrous ferric oxide and immersing in water. In no case did the colloidal hydrous ferric oxide pass through the membrane.

Unless specifically stated otherwise, the term "ratio" will mean the ratio in gram equivalents of chromium ( $1/3$  Cr) to chlorine (1 Cl).

### Observations on Results.

#### I. Continuous Dialysis.

- a. At the end of the first interval, the ratio in the diffusate was 1, or the same as in chromic chloride.
- b. This ratio increased to 1.57 without abrupt changes, and then decreased continuously to zero.
- c. The ratio within the membrane increased continuously from 2.05 to 41.6. (See curve.)
- d. More than three-quarters of the colloidal hydrated chromic oxide remained in the membrane at the end of the dialysis, when the chromium had ceased to diffuse.

#### II. Intermittent Dialysis.

- a. The ratio in the diffusate at the end of the first interval was 0.66 and was less than 1 for the three following intervals.

b. After the first four intervals the ratio was always greater than 1.

c. While there are considerable irregularities, it is evident that, in general, the ratio in the diffusate is greater the longer the interval of dialysis.

d. The ratio in the membrane, at the start, increased fairly rapidly, but very slowly after the first 400 hours. At the end of 1300 hours, the ratio in the membrane was only 6.58, *i. e.*, only slightly greater than in the diffusate. (See curve.)

e. At the conclusion of the dialysis less than one-sixteenth of the colloidal hydrous chromic oxide remained in the membrane, and the chromium had not yet ceased to diffuse.

### III. Dialysis without Changing Diffusate.

a. The ratio of Cr to Cl in the diffusate rose rather rapidly during the first 96 hours, and then more slowly, gradually approaching the value within the membrane. (See curve.)

### Interpretation of Results.

The first point which must be decided is whether the diffusates, with ratios greater than one, contain a basic chloride of chromium, or colloidal hydrous chromic oxide. It is noteworthy that the basic chlorides recorded in Gmelin-Kraut are all noncrystalline, and their compositions suggest either a mixture of simpler compounds or colloidal complexes. The existence of basic chlorides of chromium as true chemical individuals, has not been positively demonstrated. Hence we will assume that all diffusates with ratios greater than one, contain colloidal hydrous chromic oxide. This assumption is supported by the fact that these diffusates give a gel on evaporation, and, when the ratio is appreciably greater than one, yield a precipitate with potassium sulfate.

A striking difference between continuous and intermittent dialysis, as conducted in this work, is that in the former the colloidal particles finally cease to pass through the membrane, while in the latter it is seen that, after dialysis for 56 days, they continue to diffuse. A plausible as well as simple explanation of this strange behavior is that in continuous dialysis, the colloidal particles grow in size until they are too large to pass through the membrane, but in the intermittent dialysis they do not grow to such a size. We will now attempt to account for our observations on the basis of the prevailing theory of colloids, which maintains that the particles in a colloidal solution are polymers of the simplest molecule, with all the constituents in the dispersion medium more or less adsorbed. Chromic chloride in aqueous solution is hydrolyzed according to the following equations:

The addition of hydrous chromic oxide will change these equilibria somewhat, but all the substances in the above equations and the ions into which they dissociate will be present in our stock solution—in true solution in the dispersion medium and adsorbed in the disperse phase. The charges on the colloidal particles and their stability are due to the adsorption of an excess of positive ions.

**The Ratios of Chromium to Chlorine in the Diffusate.**—The rates of dialysis of the various solutes contained in a membrane immersed in water will, at the start, be proportional to the diffusion constants and to the molar concentrations. For simplicity, the solutes in the original solution will be taken as follows: colloid, chromic chloride, hydrochloric acid, and an excess of chloride ion, whose negative charge is equivalent to the positive charge on the colloidal particles. The excess of chloride ion in the dispersion medium is practically a part of the colloid and therefore will not be considered separately in the following treatment. The order of the diffusion constants is: hydrochloric acid (highest), chromic chloride, colloid (lowest). At the beginning of the dialysis, in view of the difference in their diffusion constants, we will expect in the diffusate a greater ratio of hydrochloric acid to chromic chloride than exists within the membrane in the dispersion medium, and in a short interval very little of the colloid will have diffused. Thus we may explain the low ratios in the diffusates in intermittent dialysis for the first four intervals, which are short.

An increase in the molar concentration of colloid relatively to the solutes in the dispersion medium will result in a greater relative diffusion of the colloid. The initial rapid diffusion of chromic chloride and hydrochloric acid will greatly reduce their effective concentrations in a short time, and again the relative diffusion of colloid will increase. A greater relative diffusion of colloid means a greater ratio in the diffusate. Both of the above effects exert particular influence in intermittent dialysis, the more so the longer the interval. Hence, for intermittent dialysis, the longer the interval, the greater the ratio in the diffusate.

A ratio in the diffusate less than that in the membrane will lead to a greater relative molar concentration of the colloid in the membrane, if the colloidal particles remain of the same size, *i. e.*, if the molecular weight of the colloid does not increase. Growth of the particles will have the opposite effect, not only diminishing the relative molar concentration but also the diffusion constant of the colloid.

In the continuous dialysis, the constant flow of distilled water maintains fairly uniform, or uniformly changing conditions in the diffusate, and therefore the results are far more regular than in the intermittent process. As the dialysis progresses, the ratio in the diffusate increases because the molar concentration of the colloid relatively to the solutes

in the dispersion medium increases. Since the relative concentration of the colloid in grams per liter increases throughout, the ratio in the diffusate must continue to increase unless the particles grow larger. From Interval 10, Table I, the ratio in the diffusate begins to decrease, and furthermore, the increase of this ratio from Intervals 1 to 10 is insufficient to account for the increase in the relative concentration of the colloid. Hence the data in Table I indicate that continuous dialysis is accompanied by a continuous growth of the particles.

Little need be said concerning the dialysis without changing the diffusate. It is evident that osmotic equilibrium is established in a relatively short time, while the establishment of complete uniformity between internal and external liquids takes place very slowly.

### Mechanism of the Growth of the Particles.

Two distinct processes are probably involved in the growth of the particles: first, aggregation of particles to form larger ones; second, a gradual increase of the hydrous chromic oxide in the nuclei of the particles due to hydrolysis of the chromic chloride adsorbed.

Aggregation of the particles may be explained on the basis of Bredig's theory of colloid precipitation, according to which a decrease of the potential between disperse phase and dispersion medium will cause an increase in the surface tension of the latter at its interface with the former. This increase in surface tension is conducive to aggregation. As the concentration of electrolyte in the dispersion medium relatively to the colloid diminishes during dialysis, the excess of positive ions adsorbed by the particles decreases. Thus the potential between disperse phase and dispersion medium is lowered continuously, and aggregation takes place continuously.

The large amount of water adsorbed is in no small measure responsible for the size of colloidal particles of hydrous oxides. It is also likely that adsorbed electrolytes greatly diminish the proportion of adsorbed water. Thus diffusion of adsorbed electrolytes, particularly hydrochloric acid, from disperse phase into dispersion medium, during dialysis, may result in a growth of the particles: first, by increasing the adsorbed water, and second, by progressive hydrolysis of the adsorbed chromic chloride by the adsorbed water. In the latter the chromic hydroxide formed becomes part of the nuclei.

### Summary.

1. In intermittent or continuous dialysis, in a parchment paper membrane, of a solution of hydrous chromic oxide in chromic chloride, the colloidal particles diffuse through the membrane.

2. In intermittent dialysis the ratio of chromium ( $1/3$  Cr) to chlorine (1 Cl) in the diffusate after a short time is always greater than one. In general, it is greater the longer the interval of dialysis for the same diffusate.

3. In continuous dialysis, the ratio of chromium to chlorine in the diffusate increases from 1 to a maximum of 1.57, then gradually diminishes and approaches zero.

4. In intermittent dialysis, as conducted in this research, about 6% of the original colloid, still associated with considerable electrolyte, remains in the membrane at the end of 56 days, and colloid still diffuses. This dialysis could have been continued until no colloid remained within the membrane.

5. In the continuous dialysis, 75% of the original colloid remains in the membrane. Continuing the process beyond 35 days, increases the purity of the colloid without loss of chromium, *i. e.*, only hydrochloric acid diffuses.

6. If the intervals in intermittent dialysis are made smaller, more satisfactory results are to be expected. In fact, by conducting the entire process in very short intervals, the efficiency may even exceed that of continuous dialysis. The latter procedure, however, is impractical.

7. The variations of the ratios of chromium to chlorine in the diffusates are accounted for. They indicate a gradual growth of the particles. In the intermittent process, the particles did not grow sufficiently to be retained by the membrane, whereas in continuous dialysis they did.

8. The growth of the particles is explained partly by aid of Bredig's theory of colloid precipitation and partly by assuming that the nuclei of the particles grow as the adsorbed chromic chloride is hydrolyzed by the adsorbed water.

## THE COLLOIDAL ARSENATES AND PHOSPHATES OF IRON.

BY HARRY N. HOLMES AND R. E. RINDFUSZ.

Received July 13, 1916.

The usual method of analysis of sulfide ores requires the dissolving of the sample in aqua regia and the addition of potassium chlorate or bromine to oxidize separated sulfur. After evaporation to dryness, addition of hydrochloric acid, filtration and treatment of the filtrate with ammonium hydroxide, any iron present is precipitated as ferric hydroxide. if

In attempting to apply this method to arsenopyrite, as directed by Olsen,<sup>1</sup> we failed to get the expected precipitate of ferric hydroxide. Instead a rich red solution resulted.

Assuming that ferric orthoarsenate was formed in the process, we attempted to duplicate the final result by mixing solutions of ferric chloride and disodium arsenate and treating the precipitate thus formed with

<sup>1</sup> Olsen's *Quant. Chem. Anal.*, 4th Ed., p. 172.

ammonium hydroxide. The same red solution resulted and, upon dialysis, we found it to be colloidal.

A search of the literature showed that Grimaux<sup>1</sup> had made colloidal ferric arsenate by the ammonium hydroxide peptization of precipitated ferric arsenate and, in similar manner, colloidal ferric phosphate. E. A. Schneider<sup>2</sup> also contributed something in this field but the two writers did little more than start the work.

We planned a more thorough study of the colloidal arsenates and phosphates of iron but at the very beginning found a serious difficulty. On treating ferric chloride solution with a solution of disodium orthoarsenate a rather gelatinous precipitate of  $\text{Fe}_2(\text{HAsO}_4)_3$  forms. This formula is also written  $2\text{Fe}_2\text{O}_3 \cdot (3\text{As}_2\text{O}_5) \cdot 3\text{H}_2\text{O}$ . Ordinary methods of washing failed to remove adsorbed ions. One sample washed "thoroughly" in the usual manner until the washings showed only a trace of excess arsenate was set away under water for four months. This water then contained so much soluble arsenate that it seemed as if the original precipitate had not been washed at all.

The problem of purifying the semigelatinous precipitates of ferric arsenate and phosphate was finally solved satisfactorily by mechanical disintegration of the wet precipitates. The results of that part of our investigation cast some doubt on the accuracy of many formulas given in the literature for the various phosphates of iron. Different degrees of washing precipitates that so strongly adsorb ions must certainly have given analytical evidence for many different formulas. Possibly this same doubt may extend to analysis in other fields. It was our custom to prepare the precipitate for peptization by adding a slight excess of a solution of disodium arsenate, for example, to a solution of ferric chloride and then removing this excess of soluble arsenate as well as the soluble salt formed by the reaction. The method we used has been described elsewhere.<sup>3</sup>

**Peptization by Ammonium Hydroxide.**—As observed by Grimaux,<sup>4</sup> the insoluble orthoarsenate and orthophosphate of ferric iron are quickly peptized by ammonium hydroxide into red colloids. In dilute ammonium hydroxide the action is slower, but in any case may be hastened by shaking. Several attempts to utilize the full power of a definite weight of ammonium hydroxide in peptization gave us interesting results. A sample of 24 cc. of the wet paste of ferric arsenate was shaken with 2 cc. of concentrated ammonium hydroxide in a stoppered vessel and, after a week of occasional shaking, was completely converted into a deep red sol.

<sup>3</sup> *J. Phys. Chem.*, 20, 522 (1916).

<sup>4</sup> *Loc. cit*

After standing in a tightly corked tube several months the liquid turned into a smooth solid butter of yellow-red color. Other samples acted in the same way. One, left open after treatment with concentrated ammonia, soon deposited considerable sediment, not of a buttery character. Of course this was caused by a rather rapid escape of ammonia. Approximately quantitative experiments indicated that 1 cc. of concentrated ammonium hydroxide peptizes an amount of wet paste equivalent to 1 g. of ferric arsenate. This corresponds to about 15% more ammonium hydroxide than is enough to replace the remaining hydrogens of the  $\text{Fe}_2(\text{HAsO}_4)_3$ .

Wittstein<sup>1</sup> observed that ferric phosphate could not be peptized by ammonium hydroxide unless disodium phosphate was present. We found no difficulty whatever in peptizing the thoroughly washed precipitate of ferric phosphate.

During dialysis of the two colloids mentioned, considerable osmotic pressure developed. One sample of ferric arsenate sol rose, in a few weeks, to a level of 9.5 cm. above the water outside the dialyzing tube. After some time this dropped rather rapidly, not, however, because of any break in the dialyzing membrane (goldbeater's skin). It would seem that this action may have been influenced by changes in the size of the colloidal aggregates through removal of ions and instability of phases. Not long after the fall in osmotic pressure small lumps of gel appeared.

Ammonia was gradually removed during dialysis and the dialysates for some time showed a test for arsenate ion. This removal of ammonium arsenate is discussed in detail under the heading "Properties of the Colloid." After continued dialysis for a few months the sol of ferric arsenate formed an excellent dark red gel. Grimaux failed to obtain this gel. In a small dialyzer the gel was solid and like a good fruit jelly in texture but in a large dialyzer the gel was lumpy, possibly due to greater agitation in changing the water. This gel could not be peptized again by ammonium hydroxide. When dissolved in hydrochloric or nitric acid and dialyzed a poor gel resulted.

From this point on we will discuss ferric arsenate, but it is to be noted that all results, unless otherwise stated, were duplicated with ferric phosphate.

**Properties of the Colloids.**—The sol of ferric arsenate is quite like colloidal ferric hydroxide (or "hydrated ferric oxide") in appearance, varying from a light cherry to a black-red with increase in concentration. The question arose whether this is not, after all, merely colloidal ferric hydroxide with adsorbed arsenate. Experiments readily showed that the colloid was negatively charged whereas colloidal ferric hydroxide is positive. Subjected to prolonged electrolysis in a 25 cm. tube with 18

<sup>1</sup> Comey's "Dictionary Chem. Solubilities," p. 304.

volts and less than 0.1 ampere current the red particles migrated to the positive pole and coagulated. Furthermore the ferric arsenate sol was extremely sensitive to an increase in valence of positive ions while an increase in valence of negative ions was without effect, a simple proof of the negative nature of the colloid. There was no difference in the amount of 0.02 *N* sodium chloride or 0.02 *N* disodium phosphate needed for coagulation of the colloid. Evidently the trivalent negative phosphate ion exerted just as little coagulating power as did the univalent negative chloride ion. On the other hand coagulation was produced by much less 0.02 *N* barium chloride and by very much less 0.02 *N* aluminium chloride.

The well-dialyzed sol of ferric arsenate is quite stable. One sample, over a year old at this date, shows no sign of settling. It is not coagulated by boiling but is very sensitive to polyvalent positive ions and is coagulated by considerable alcohol. A very little nitric or hydrochloric acid produces a coagulum, but this dissolves easily in a slight excess of the acid. Unless very dilute acid is used and added slowly no coagulum shows but the deep red color turns to the light yellow of a ferric chloride solution. Addition of excess ammonium hydroxide to this solution gives a precipitate, apparently ferric hydroxide, leaving a colorless liquid above. This point is discussed later. Evaporated spontaneously in the air the colloid is not reversible.

The thoroughly dialyzed colloid contains no free ammonia and on heating with sodium hydroxide not enough combined ammonia is released to affect litmus. Dialyzed colloidal ferric arsenate was evaporated to dryness on the water bath and duplicate samples analyzed. No. 1 contained 38.0% iron and 15.8% arsenic; No. 2 contained 38.3% iron and 15.6% arsenic. These values correspond to the formula  $\text{FeAsO}_4 \cdot \text{Fe}_2\text{O}_3 \cdot x\text{H}_2\text{O}$  which might be called basic ferric orthoarsenate. Another sample prepared at a different time was dialyzed until lumps of gel appeared. The mixture of sol and gel was analyzed for the ratio of iron to arsenic, which was found in satisfactory agreement with the above formula. The removal of soluble arsenate, doubtless as ammonium arsenate as previously mentioned, accounts for the change in formula from  $\text{Fe}_2(\text{HASO}_4)_3$  of the fresh precipitate to  $\text{FeAsO}_4 \cdot \text{Fe}_2\text{O}_3 \cdot x\text{H}_2\text{O}$  of the dialyzed colloid. It was suggested by W. Metcalf that the original precipitate was decomposed by water, thus accounting for the change in composition on dialysis. Lachowicz<sup>1</sup> states that such is the case. However, our precipitate after the special purification previously mentioned was kept under distilled water three months and this water gave no test for arsenate ion and only a slight test for chloride ion. It seems probable, therefore, that this precipitate is not decomposed by water and that Lachowicz's observation must have applied to an incompletely washed precipitate.

### Absorptive Power of the Colloids.

Ferric hydroxide was dissolved in a solution of ferric chloride in order to obtain colloidal ferric hydroxide and ferric ions in the same solution. Without dialyzing, this was treated with a solution of sodium arsenate. The white precipitate of ferric arsenate appeared an instant before the red coagulum of ferric hydroxide. Naturally the trivalent negative arsenate ions neutralized the positive charge on the colloidal ferric hydroxide and coagulation followed. But at the same time ferric ions from the ferric chloride reacted with arsenate ions to precipitate white ferric arsenate. This simultaneous precipitation and coagulation insured an intimate mixture of the insoluble ferric hydroxide and ferric arsenate. The entire precipitate was readily peptized by addition of ammonium hydroxide into a deep red sol.

The peptizing action of ammonium hydroxide on ferric arsenate has already been discussed, but even an excess of this base has no such effect on precipitated ferric hydroxide. The ferric hydroxide precipitate has simply been adsorbed by the colloidal ferric arsenate and thus carried into suspension. To test this point further a finely divided precipitate of ferric hydroxide was shaken in water with an excess of finely divided precipitate of ferric arsenate. Addition of ammonium hydroxide formed an excellent sol of unusually deep red color and with a greenish "bloom." A small amount of sediment slowly settled on standing. This deep color and bloom were duplicated by adding very little colloidal ferric hydroxide—less than enough for mutual precipitation—to the dialyzed ferric arsenate. The bloom was apparently due to the presence of aggregates somewhat larger than those of the clearer colloids.

The above experiments furnish further evidence that colloidal ferric arsenate is not colloidal ferric hydroxide with adsorbed arsenate. We have loaded our negative colloid with a positive colloid, ferric hydroxide, up to a point short of complete discharge. When that limit is reached adsorption ceases and precipitation results.

Ferric chloride solution, as discussed later, dissolves precipitated ferric arsenate. If less than one-tenth enough to dissolve the precipitate is added the further addition of ammonium hydroxide forms a red colloid. Of course the ammonium hydroxide peptizes the ferric arsenate and at the same time forms some ferric hydroxide which is adsorbed by the colloidal ferric arsenate. If more than enough ferric chloride to peptize the arsenate is added there is some precipitation with ammonium hydroxide, but a red sol may also form. If still more ferric chloride is used, addition of ammonium hydroxide may cause complete precipitation, leaving a colorless liquid above. The excess ferric hydroxide, if formed first as a positive colloid, has coagulated the negative colloid, ferric arsenate, formed at the same time. Less than enough ferric hydroxide to discharge com-

pletely the negative colloid results in the adsorption of the ferric hydroxide and little or no precipitation.

This phenomenon, also observed in the adsorption of aluminium hydroxide and other hydroxides by colloidal ferric arsenate, is similar to that reported by Fisher and Herz.<sup>1</sup> They found that if, in a mixture of solutions of ferric and chromium salts, the chromium salt is in large excess, the addition of an excess of a solution of sodium hydroxide forms colloidal chromium hydroxide carrying into the sol all the iron as adsorbed ferric hydroxide. With a much smaller excess of the chromium salt both sol and precipitate may result while if the ferric salt is in excess there is no sol but complete precipitation.

We found other examples of hydroxide adsorption. A small amount of a solution of aluminium chloride was added to an excess of precipitated ferric arsenate and upon addition of ammonium hydroxide a sol resulted with no precipitation. An excess of aluminium chloride resulted in complete precipitation. Chromium chloride and lead nitrate were substituted for the aluminium chloride with similar results.

These adsorption experiments lead to an explanation of the fact that dialyzed colloidal ferric arsenate treated with excess hydrochloric or nitric acid yields a precipitate when ammonium hydroxide is added. In this case the ammonium hydroxide does not exert its usual peptizing action. If a fresh precipitate of  $\text{Fe}_2(\text{HAsO}_4)_3$  is dissolved in hydrochloric or nitric acid and ammonium hydroxide added the same precipitation results with some sol remaining. If considerable excess arsenic acid is mixed with ferric chloride solution and excess ammonium hydroxide added, both the white insoluble ferric arsenate and the red insoluble ferric hydroxide are seen. On shaking a deep red sol forms. If a smaller amount of arsenic acid is used the addition of ammonium hydroxide precipitates ferric hydroxide with possibly a little of the sol remaining.

In the equilibrium indicated above most of the iron is on the right of the equation. Addition of ammonium hydroxide must neutralize the hydrochloric acid and thus disturb the equilibrium to the left, causing the appearance of white insoluble ferric arsenate. At the same time ammonium arsenate is formed but this reacts readily with ferric chloride to form more ferric arsenate. Some ferric hydroxide must also be formed by the action of the base. An excess of ammonium hydroxide may peptize the white precipitate of ferric arsenate into a red colloid. However, unless considerable excess of arsenic acid is used any colloidal ferric arsenate formed is adsorbed and precipitated, at least in part, by the coagulum of ferric hydroxide. This needed excess of arsenic acid is not obtained when a precipitate of  $\text{Fe}_2(\text{HAsO}_4)_3$  is dissolved in hydrochloric

<sup>1</sup> *Z. anorg. Chem.*, 31, 352 (1902).

acid but it must be added. The ability of peptized ferric arsenate to adsorb ferric hydroxide is limited, as previously stated. It is also probable that the equilibrium

is shifted to the left by the action of excess arsenate ion on the ferric ion.

In the case of the dialyzed sol,  $\text{FeAsO}_4 \cdot \text{Fe}_2\text{O}_3 \cdot x\text{H}_2\text{O}$ , treated with hydrochloric acid the excess of ferric chloride over the arsenic acid formed is too great to yield a colloid on treatment with ammonium hydroxide. In other words, the ratio of three atomic weights of iron to one of arsenic gives too great an excess of ferric chloride when dissolved in hydrochloric acid. This is the ratio in the dialyzed colloid but it must be remembered that this is not the ratio of iron to arsenic that existed when the sol was formed in the presence of ions. That ratio was represented by the formula  $\text{Fe}_2(\text{HASO}_4)_3$  and the change to  $\text{Fe}_2\text{AsO}_4 \cdot \text{Fe}_2\text{O}_3 \cdot x\text{H}_2\text{O}$  came about slowly as the ions dialyzed out.

**Peptization by Substituted Ammonias and Other Bases.**—A water solution of pure methyl amine quickly converted the precipitate of ferric arsenate into the characteristic dark red colloid. On dialysis a firm red gel formed after a few weeks. Aqueous solutions of dimethylamine and tetramethyl ammonium hydroxide showed just as great peptizing power, but the action of our trimethyl amine was much less marked. To vary the series of substituted ammonias we used diethyl amine with success. Aniline and pyridine were shaken with the wet precipitates but with little or no result.

Sodium hydroxide or potassium hydroxide solutions, carefully used, peptized ferric arsenate to a red sol, contrary to the statements of Grimaux. Very dilute base, about 0.1 *N*, must be added, drop by drop, with shaking, and great care taken to avoid an excess. Otherwise the colloid is precipitated as fast as formed. Doubtless such a lack of caution accounts for Grimaux' failure to obtain the colloid by sodium hydroxide peptization. Dialysis yields a rough coagulum rather than a compact gel.

Attempts to employ calcium hydroxide or barium hydroxide as peptizing agents failed, although the white precipitate of ferric arsenate developed a red tint. If there was an intermediate colloidal state it was not apparent, for the bivalent positive ions quickly coagulated the negative colloid. Solutions of sodium carbonate and ammonium carbonate showed a slight peptizing power.

These results suggest the possibility that the hydroxyl ion is a peptizing agent.

**Peptization by Ferric Chloride.**—Grimaux<sup>1</sup> states that a ferric chloride solution dissolves precipitated ferric arsenate and that, on prolonged

<sup>1</sup> *Loc. cit.*

dialysis, a transparent reddish yellow gel is formed. He did not pursue this line of investigation, not even experimenting with ferric phosphate.

We duplicated his work in making the sol and gel of ferric arsenate and obtained similar results with ferric phosphate. Grimaux records a difference in color of the ferric arsenate precipitated from ferric chloride, depending on whether sodium or potassium arsenate was used, the latter, he observes, giving a yellower precipitate. We found no such difference when care was taken to use a slight excess of the alkali arsenate. However, a very slight excess of ferric chloride exerts a peptizing action, developing a yellow to red tint. This, doubtless, accounts for the difference in color observed by Grimaux.

The amount of ferric arsenate peptized by ferric chloride solution is greatly increased by heating and the sol is a deeper red. Such a sol is not so stable and coagulates, in part, on dialysis.

The fact that ferric arsenate is so easily peptized by ferric chloride is good reason for using a slight excess of disodium arsenate solution on a solution of ferric chloride in preparing the precipitate. This excess of disodium arsenate can be removed by the method previously described.

The gel formed by the peptization of ferric arsenate by a solution of ferric chloride and subsequent dialysis is of excellent texture and looks much like a good fruit jelly. A sample retained its shape for several months when placed in 95% alcohol. Exposed to the air it dries down to a coarse powder. On standing sealed the gel slowly contracts. A change to a less hydrated phase is shown by the appearance of water around the gel. One gel had stood in a sealed tube for three months and had squeezed out considerable water. The water was rich in hydrochloric acid but gave only a slight test for iron. This shows that ferric chloride, included in the gel, had been hydrolyzed, the resulting colloidal ferric hydroxide being adsorbed, while the hydrochloric acid readily diffused throughout the water. Of course longer dialysis would have removed more of the hydrochloric acid. The gel may be dissolved in ammonium hydroxide to the characteristic sol which behaves exactly like that formed by the ammonium hydroxide peptization of ferric arsenate. It forms a good gel on dialysis and may then be redissolved in ferric chloride and a second gel formed on dialysis. A better structure of gel is secured if the ferric arsenate is peptized by ferric chloride solution immediately after precipitation. Delay from any cause, washing or otherwise, seems to permit an unfavorable change in physical condition. The gel forms after about two weeks' dialysis.

We next tried treating the precipitates of the arsenates of the common metals with a solution of ferric chloride. The arsenates of lead and mercurous mercury gave sols and white precipitates of the chlorides. On dialysis after filtration these sols gave the characteristic gels of ferric

arsenate. We found, also, that the arsenates of other metals gave the same gels containing none of the metal whose arsenate was used. This was true of arsenates of all the common metals except stannic tin and the soluble arsenates of the alkali group. Dialysis removed all the soluble products of the reaction, thus disturbing the equilibrium and leaving the insoluble ferric arsenate in the highly hydrated gel form. Ferrous arsenate dissolved in a solution of ferric chloride gave, on dialysis, an excellent red gel which contained both ferrous and ferric iron. In most cases these gels formed when nearly all the chloride ion was gone but there were a few instances where considerable remained. This then dialyzed out very slowly.

A sample of ferric arsenate in a solution of chromium chloride on dialysis gave a good green gel which contained only a trace of iron. This shows that in the relation of chromium to iron, at least, it is a matter of mass action, depending on which salt is in excess to determine whether we get the arsenate of iron or of chromium in the gel form.

Two samples of cadmium arsenate in ferric chloride solution were dialyzed. One gave an excellent red gel in about three weeks; the other in a few days gave a yellowish butter. This contracted but little and took three months to dialyze out all the chloride ions. At the end of that time it was more nearly a gel in texture but was still quite buttery and light yellow in color. This same difference was observed with two samples of lead arsenate in ferric chloride solution. The probable explanation is that we get the quickly formed butter when there is not enough excess ferric chloride solution, and on dialysis this slight excess is removed too suddenly for the change to gel form to take place. This is substantiated by the fact that some of the butter from the lead arsenate was redissolved in a large excess of ferric chloride solution and gave, on dialysis, a splendid red gel. The behavior of the mixture of solutions of ferric chloride and arsenic acid greatly strengthens this view.

After this work on gels had been completed we found that E. A. Schneider<sup>1</sup> had already done a small amount of work along the same line. He had dialyzed the sol of calcium phosphate in ferric chloride solution and had gotten the gel of ferric phosphate as soon as nearly all the chloride ion was removed. He had also observed that this gel dissolved in ammonium hydroxide and on dialysis lost phosphate. This agrees with our observations on this gel and on the original sol of ferric phosphate or arsenate in ammonium hydroxide. He found that if the gel was treated with potassium hydroxide there was a precipitation of ferric hydroxide, while nearly all the phosphate went into solution. We had not tried the addition of the base directly, but found similar results with the ammonia gel or sol when treated with acids and the base added. Schneider sug-

gested this as a method for the separation of iron and phosphorus and extended it to calcium. The calcium phosphate dissolved in ferric sulfate giving a precipitate of calcium sulfate. On addition of potassium hydroxide solution to the filtered sol the iron was precipitated as hydroxide, leaving the phosphate in solution. His aim was to get a method of analysis applicable to humus.

Sodium metaphosphate treated with excess ferric chloride solution gave the characteristic sol and, on dialysis, a good gel of ferric metaphosphate. The pyrophosphate on similar treatment yielded a most excellent deep red gel of ferric pyrophosphate. Ferric hypophosphite gave sols with ferric chloride solution, hydrochloric acid or nitric acid. On dialysis each of these sols yielded a rather poor gel.

**Peptization by Sulfates.**—Aside from any connection with Schneider's work we had already tried using sulfates instead of ferric chloride solution as peptizing agents. On adding to a solution of sodium arsenate an excess of a solution of ferric alum, or of aluminium sulfates, or of chrome alum, the same results were observed as when the chlorides of these metals were used. The sols were apparently very stable. One sample made by treating sodium arsenate with excess of ferric ammonium sulfate solution has stood undialyzed for four months with no sign of settling. On dialysis, however, there is great difference. Inside of a few days a powder begins to form on the walls of the dialyzer and then on the membrane and after a few more days the colloid settles out entirely as a powder. This was found to be the case every time a sulfate was used as a peptizing agent.

**Peptization by Hydrochloric or Nitric Acids.**—The question naturally suggests itself whether the salt (such as ferric chloride) or the acid from hydrolysis does the peptizing. The dialysates from ferric arsenate in ferric chloride solution were acid for ten days. Evidently the way to settle the point was to try hydrochloric acid instead of ferric chloride solution as a peptizing agent. We found that on dialysis of the colorless solution of well washed precipitate in hydrochloric or nitric acid ferric ion diffused through the membrane for about four days. Then a color began to develop and after a few more days a light yellow gel of excellent texture was formed. This gel could be redissolved in acid and the gel obtained again on dialysis or the gel from ferric chloride dissolved in acid and another gel obtained on dialysis. It has been mentioned before that the gel from the ammonium hydroxide peptization could be dissolved in acid and formed again on dialysis. The gel from the pure acid was not so red as the one from ferric chloride solution because, no doubt, of the lack of adsorbed ferric hydroxide. In the case of the ferric chloride peptization the large excess of ferric chloride, the probability that the hydrochloric acid from hydrolysis reacts to dissolve the arsenate, thus

causing more hydrolysis, and the fact that so much acid dialyzes out, led us to expect a very considerable adsorption of ferric hydroxide. Nitric acid may be used instead of hydrochloric but sulfuric acid gives, on dialysis, the powder described under sulfate peptization.

Hydrochloric acid on ferric arsenate probably forms ferric chloride and arsenic acid, or an acid ferric arsenate. The solution thus formed passes from reddish yellow to light yellow to colorless as the acid is added and, on dialysis, this color change reverses. The removal of the hydrochloric acid by dialysis disturbs the equilibrium, reversing the reaction and slowly reforming ferric arsenate, first in the sol and later in the gel condition. We thought it possible to duplicate these results by starting with the substances on the other side of the equilibrium. Arsenic acid was added to ferric chloride solution until the color was nearly gone and the solution dialyzed. In about two weeks there resulted a splendid gel of about the same color as the gel from ferric arsenate in hydrochloric acid. Similar results were obtained using diluted phosphoric acid in ferric chloride solution. If too concentrated solutions were used a powder and then a butter was obtained. This confirms our conclusions about the butter as given above.

**Peptization of Other Salts by Ammonium Hydroxide.**—The pyrophosphate of ferric iron peptized readily in ferric chloride solution forming a red sol. After two months' dialysis an excellent compact deep red gel resulted. Ferric metaphosphate was also peptized to a red sol by a little very dilute ammonium hydroxide but was coagulated again by any excess. It yielded no gel on dialysis. Efforts to peptize ferric hypophosphite by ammonium hydroxide failed. Ferric arsenite was readily peptized by ammonium hydroxide to a red-yellow sol. Dialysis did not produce a real gel. Chromium arsenate and phosphate were peptized to a slight extent only by ammonium hydroxide. The same is true of the arsenate of aluminium. The arsenates of zinc and nickel were peptized by this base but on dialysis these colloids were precipitated.

**Sols and Gels of Aluminium and Chromium Salts.**—When a solution of aluminium chloride was added in excess to sodium arsenate solution the precipitate first formed was redissolved and, on dialysis, a colorless gel formed on the dialyzer. This gel seemed to retard the diffusion of ions, for when there was about one-fourth inch of gel on the membrane the dialysates showed almost no chloride ions while the sol above the gel was rich in chlorides. On changing this sol to another dialyzer a gel formed. However, the disturbance at the time of transfer caused the gel to be lumpy. We tried one sample with which we shook the dialyzer every day to keep the sol uniform. The gel developed from top to bottom but in lumps. The aluminium arsenate gels were not nearly as good as those of iron. With chromium arsenate the results were very like those

with aluminium. The gels were perhaps a little better and of greenish color.

### Summary.

1. The precipitated arsenates and phosphates of ferric iron are rather gelatinous and difficult to wash free from adsorbed ions. However, they may be purified by repeated shaking with sand and a large amount of water followed by decantation or filtration.

2. Ferric orthoarsenate and orthophosphate may be peptized by comparatively small amounts of ammonium hydroxide, yielding stable colloids. On long-continued dialysis these were found, contrary to the experience of Grimaux, to form excellent deep red gels. The composition of both sol and gel of the arsenate correspond closely to the formula  $\text{FeAsO}_4 \cdot \text{Fe}_2\text{O}_3 \cdot x\text{H}_2\text{O}$ . The change in composition from that of the precipitated arsenate and the formation of the final sol and gel are brought about by the removal of ammonium arsenate during dialysis. The same is true of the phosphate.

3. The peptization mentioned in (2) is probably due to the action of the hydroxyl ion since, with limitations, other hydroxides may be substituted for ammonium hydroxide and substituted ammonias may be used as peptizing agents. The colloid formed by using a water solution of methyl amine yielded, on continued dialysis, a splendid gel of a deeper red color than the others.

4. Either colloid has great adsorptive power, carrying into suspension with it other insoluble hydroxides at the time of its peptization. This power, however, is greatly lessened by the removal of arsenate during dialysis.

5. Ammonium hydroxide also peptizes ferric pyrophosphate, ferric metaphosphate and ferric arsenite. With arsenates and phosphates of chromium and aluminium there seems to be very little peptization. With the arsenates and phosphates of zinc and nickel unstable sols are formed, settling out on dialysis.

6. Ferric orthoarsenate or orthophosphate is peptized by ferric chloride solution as found by Grimaux and yields, on dialysis, an excellent red gel after removal of most of the chloride ion. In similar manner the orthoarsenate or orthophosphate of chromium or aluminium are peptized by solutions of chromium chloride or aluminium chloride and form gels on dialysis.

7. The precipitated orthoarsenates or orthophosphates of any of the common metals are peptized in ferric chloride solution and yield, on dialysis, gels of ferric arsenate or phosphate. If the ferric chloride solution is overloaded with the arsenate or phosphate, a butter is formed which is very slow to give up its adsorbed ions.

8. If a solution of a sulfate is used as the peptizing agent, instead of a

chloride as mentioned in (6), a sol is formed stable on standing but forming a powdery sediment on dialysis and completely settling out.

9. In all examples of peptization by salts as mentioned in (6), (7) and (8) the action is due to acid hydrolysis, as shown by the fact that hydrochloric or nitric acid may be used as peptizing agents with equally good results. The sols formed by acids give excellent gels on dialysis but lighter in color than those formed from ferric chloride solution. If sulfuric acid is used the results are those observed in the use of any sulfate as the peptizing agent. There are at least two kinds of peptization of these arsenates and phosphates, that by acids and that by bases.

10. The formation of the sol and gel in the case of the acid peptizations is due to the disturbance of the equilibrium by dialysis. This is shown by the fact that good gels may be formed by dialyzing dilute mixtures of ferric chloride solution and arsenic or phosphoric acid, the phosphoric acid giving a gel excellent in clearness as well as in texture.

11. The metaphosphate, pyrophosphate and hypophosphite of ferric iron behave like the orthophosphate in peptization by acids and ferric chloride. Ferric pyrophosphate in ferric chloride solution formed a splendid deep red gel on dialysis.

## THEORY OF COLLOIDS.

BY JOHN ARTHUR WILSON.

Received July 27, 1916.

The object of the present paper is the promulgation of further reasoning in favor of the "complex" theory of colloid formation and the elucidation of the very interesting and important conclusions which follow. The fundamental assumption of this theory is that the colloidal state in sols owes its stability to the formation of a complex between the particles of the disperse phase and certain substances present or formed in the dispersion medium during the preparation of the colloid. The sols of the noble metals have been cited as an argument against this theory, but Beans and Eastlack<sup>1</sup> have shown that the presence of chloride, bromide, iodide, or hydroxide ions in concentrations from 0.00005 *N* to 0.005 *N* has a marked stabilizing effect on gold sols and that the colloid particles become negatively charged. In concluding, these authors consider that the electrical synthesis of colloids consists of a thermo-mechanical dispersion of the metal, followed by the formation of a colloidal complex between the dispersed metal and certain ions present in the medium.

The assumption of the formation of such a complex between any colloid particles and electrolytes present in the dispersion medium is not unreasonable. Carbon is a typical *adsorbing* agent and happily one, the stability of whose compounds has been extensively investigated. The

<sup>1</sup> THIS JOURNAL, 37, 2667-83 (1915).

data leading to the formulation of Baeyer's Strain Theory indicates that the four valencies of the carbon atom are directed toward the vertices of a regular tetrahedron, of which the carbon atom is the center. This being true, any atom *within* a given particle of carbon will attract and be attracted by the atoms immediately surrounding it, but one at the surface is attracted only towards atoms of the particle and consequently has one or more of its valencies directed away from the particle, and therefore unsatisfied. In a lump of carbon this free or residual valency might be relatively insignificant but would increase to huge proportions as the carbon became more and more highly dispersed. It is probable that every substance possesses a certain amount of residual valency at its surface, which tends to cause it to combine with substances approaching its surface. As in chemical combination in general, such combination is probably selective. Indeed, Beans and Eastlack (*Loc. cit.*) have shown that the presence of fluoride ions does not stabilize gold sols, while Lenher<sup>1</sup> has shown that gold fluoride is incapable of existence, not only in the presence of water, but under ordinary laboratory conditions.

Apparently the colloid particle takes its electrical charge from the ions with which it combines, or in some cases, acquires a charge by ionizing itself. Such a charge seems to be necessary to the stability of the colloid state in sols, which is explained to some extent by the fact that particles with like charges tend to repel each other, thus preventing coalescence.

Associated with any charged particle there will be a number of ions of opposite charge, which cannot be separated from the surface of the particle, excepting by very small distances, or by being replaced by other ions of the same sign, which means that the distribution of ions in the layer of solution surrounding the particle will be different from that in the bulk of the dispersion medium, a condition to which Donnan's<sup>2</sup> work on membrane equilibria can be applied. Donnan considers an aqueous solution of a salt, NaR, such as Congo red, in contact with a membrane which is impermeable to the anion R' and the nonionized salt, but will allow Na<sup>+</sup> or any other ion to pass freely through it. On the other side is an aqueous solution of sodium chloride, which will diffuse from its Solution II into the Solution I of NaR. When equilibrium is established, if a small virtual change is made reversibly at constant temperature and volume, the free energy will remain unchanged, *i. e.*, no work will be done. The change here considered is the transfer of  $\delta n$  moles of Na<sup>+</sup> and Cl' from II to I. The work which equals zero is

$$\delta n RT \log \frac{[\text{Na}^+]_{\text{II}}}{[\text{Na}^+]_{\text{I}}} + \delta n RT \log \frac{[\text{Cl}^-]_{\text{II}}}{[\text{Cl}^-]_{\text{I}}} = 0$$

or

<sup>1</sup> THIS JOURNAL, 25, 1136 (1903).

<sup>2</sup> Z. *Electrochemie*, 17, 572 (1911).

$$[\text{Na}^+]_{\text{II}} \times [\text{Cl}^-]_{\text{II}} = [\text{Na}^+]_{\text{I}} \times [\text{Cl}^-]_{\text{I}}.$$

By a continuation of this reasoning it can be shown that whatever diffusible binary electrolytes be added to Solution II, when equilibrium is established, the *products* of concentrations of any pair of diffusible and oppositely-charged ions will be equal in the two solutions.

If a substance is dispersed to the colloid state in a solution of the electrolyte MN and combines with a portion of  $\text{M}^+$  (not necessarily in equivalent quantity from a chemical standpoint), then at the surface of the colloid particles there will be a certain concentration of  $\text{N}'$  bound by electrochemical attractions to the colloid. This surface layer of solution will also contain  $\text{M}^+$  and  $\text{N}^-$  and will thus bear the same relation to the bulk of solution as did Solution I to Solution II in Donnan's work just quoted, and consequently the product  $[\text{M}^+] \times [\text{N}^-]$  will be equal in the surface layer and bulk of solution, and since the concentrations of  $\text{M}^+$  and  $\text{N}^-$  are *unequal* in the surface layer and *equal* in the bulk of solution, *the total concentration of ions will be greater in the former than in the latter.*

In the bulk of solution let  $x$  = concentration of positive or negative ions.

In the surface layer surrounding particle let  $y$  = concentration of ions of same sign as charge on the colloid particle.

$z$  = concentration of ions bound to the colloid by electrochemical attractions.

Therefore  $y + z$  = concentration of ions of opposite sign to that on the colloid particle.

Let  $e$  = excess of concentration of diffusible ions of the surface layer over that of the bulk of solution.

In order to keep the reasoning as simple as possible only binary electrolytes will be considered, although it will be obvious that the reasoning can be extended to include ions of any valency. From the law of "equality of products" just discussed

$$x^2 = y(y + z)$$

and since

$$\begin{aligned} 2x + e &= 2y + z \\ z &= \sqrt{4ex + e^2}. \end{aligned}$$

If unit quantity of colloid and unit volume are considered,  $z$  represents the quantity of electrolyte combined with the colloid. But the generally accepted empirical formula for adsorption (using the same system of notation) is

$$z = kx^{1/p}$$

where  $p$  represents a constant, usually about 2, so that generally

$$z = k\sqrt{x}.$$

The similarity of the equations is striking and in certain cases, and

within limits, they would give similar curves, but they are not identical, and here it should be noted that the latter formula is at best only empirical, while the former follows from well-founded assumptions.

The different distribution of ions in the surface layer and bulk of solution will result in a difference of potential, the formula for which is given by Donnan<sup>1</sup> as follows:

$$E = \frac{RT}{F} \log \frac{1}{\lambda}$$

Or, in the notation adopted in this paper,

$$E = \frac{RT}{F} \log \frac{x}{y} = \frac{RT}{F} \log \frac{2x}{-z + \sqrt{4x^2 + z^2}}$$

But  $z$  has a limiting maximum value, since the amount of electrolyte which can combine with a colloid of definite degree of dispersion is limited by the amount of residual valency at the surface, or, in the case of an ionizing colloid, the portion ionized cannot exceed the whole. Hence,

$$\lim_{x \rightarrow \infty} E = \frac{RT}{F} \log \frac{2x}{\sqrt{4x^2}} = 0,$$

proving that the difference of potential existing between the surface layer surrounding the colloid particle and the bulk of solution will diminish as the concentration of electrolyte is increased, after the combination of colloid and electrolyte has reached or neared its maximum. When this difference of potential has become sufficiently small a condition is established which is favorable to the coalescence of the particles. Assuming that a given potential difference is required for the maintenance of the colloid state in sols, the amount of electrolyte required for precipitation of the colloid will depend upon the maximum value for  $z$ . In the case of suspensoids this is probably very small, while for many emulsoids it is known to be comparatively high.

Where a charged particle combines directly with an ion of opposite sign, precipitation must follow. The cause of the co-precipitation of oppositely-charged colloids is equally obvious, but it might be well to point out in passing that the rate of this precipitation might be controlled by suitable regulation of the concentration of electrolytes in the dispersion medium. Similar lines of reasoning explaining the swelling and contracting action of electrolytes upon colloid jellies have been worked out by H. R. Procter and the author and appear elsewhere.<sup>2</sup> Whatever herein expressed may seem opposed to the generally-accepted views on colloids can be tested as the formulas derived are quantitative in character. The author expresses the hope that they may lead a step nearer to the goal of colloid chemists.

# THE HYDROGEN AND CHLORINE ION ACTIVITIES OF SOLUTIONS OF POTASSIUM CHLORIDE IN 0.1 MOLAL HYDROCHLORIC ACID.

By HERBERT S. HARNED.

Received July 1, 1916.

In a recent communication,<sup>1</sup> measurements of cells of the type

and

showed that the hydrogen ion activity of the acid and the hydroxyl ion activity of the base were increased by the addition of neutral salts. Further, the evidence obtained with the acid and salt solutions showed that the increase in hydrogen ion activity on the addition of salts differed little, if at all, for the different salts used. At that time a plot was predicted which was thought to give the change in electromotive force of the hydrogen electrode with the change of salt concentration in the acid. Such a change in electromotive force is obviously equal to the electromotive forces of the cells

at different salt concentrations (*c*). From these, if the hydrogen ion activity of the acid is known, the hydrogen ion activity of the acid-salt solutions can be computed.

The most important difficulty previously encountered in obtaining the electromotive forces of the cells

consisted in the elimination of the liquid potentials set up between the saturated potassium chloride solution and the solutions of the salt in the acid. Saturated potassium chloride, many times recommended for the elimination of liquid potentials, was shown to give different potentials against solutions of different concentrations of the same salt, and against the same concentrations of different salts. A similar series of measurements had been made by Poma<sup>4</sup> who used a saturated ammonium nitrate solution for the elimination of the liquid potentials. If Poma's results are compared with those mentioned above, it is clear that the liquid

<sup>1</sup> THIS JOURNAL, 37, 2460 (1915).

<sup>2</sup> This symbolizes a series of cells containing salt at a series of concentrations (*c*).

<sup>3</sup> The double bar means that the liquid potential has been eliminated.

<sup>4</sup> *Z. physik. Chem.*, 87, 197 (1914); 88, 671 (1914).

potentials produced between the solutions of the salts in the acid and the ammonium nitrate solution are greater than those produced when potassium chloride is used. The important point is that neither potassium chloride or ammonium nitrate eliminates these liquid potentials.

For this reason it is desirable to determine the electromotive forces of the cells

by the use of a method which is free from these liquid potential difficulties. In this paper such a procedure has been adopted.

#### The Method of this Communication.

If potassium chloride be added to the hydrochloric acid in the cell

a change in electromotive force will occur. The total effect will be due to the sum of the variations of the two electrodes. Any change in the hydrogen ion activity or the chlorine ion activity will be registered at the hydrogen electrode and the calomel electrode, respectively. This total change in electromotive force will be equal to the sum of the changes in electromotive forces of the cells

and

when the concentration of the potassium chloride is the same.

If the ion activities of 0.1 *M* potassium chloride and 0.1 *M* hydrochloric acid are the same, then the electromotive forces of the last series of these cells would equal the electromotive forces of the cells

In this communication the following procedure has been adopted:

(1) The electromotive forces of the cells

have been measured. From these, the drops in electromotive forces of the cell

on the addition of potassium chloride of different concentrations to the acid have been computed. The electromotive forces of the cells

have then been calculated by subtracting the electromotive forces of the cells

<sup>1</sup> Thus, as will be seen later, a concentration of 0.06 *M* salt in 0.1 *M* hydrochloric acid is compared with 0.16 *M* salt.

obtained from the plot X of the earlier communication from the drops in electromotive forces of the cell

on the addition of potassium chloride.

(2) The electromotive forces of the cells

have been measured, and from these the electromotive forces of the cells

have been obtained by eliminating the liquid potential by means of a suitable formula.

(3) Having obtained the electromotive forces of the cells

and

by the above methods, we are in a position to test the contentions made in the previous article. The last part of this paper will contain a discussion of the values thus obtained and the calculation of the hydrogen and chlorine ion activities of the acid-salt solutions from these values.

### Measurements.

1. Cells,  $\text{H}_2 \mid \text{KCl (c) in HCl (0.1 M), HgCl} \mid \text{Hg}$ .—A cell in the form of an H-tube was used, one limb of which contained the calomel electrode, the other the hydrogen electrode. Precautions were taken to separate thoroughly the two limbs of the apparatus, and in no case here recorded did the hydrogen electrode take on a gray coating of mercury. Carefully purified chemicals were employed. Before making up the cell, the calomel paste was washed by decantation six or seven

times with the solution to be introduced in the cell and the mixture was allowed to stand three days at 25° before being used. Finally, the cells were kept in a thermostat for a period of two to four days until further shaking of the calomel electrode caused a variation of less than 0.05 of a millivolt over a period of twenty-four hours. All measurements were carried out at 25° with a maximum variation of 0.03°.

Table I shows the values obtained.

The correction of the pressure of the hydrogen was computed by the formula  $(RT/2F) \ln 1/p$  as in the previous communication. The corrected electromotive force is what the electromotive force of the cell would be if the pressure of the hydrogen in the cell was one atmosphere<sup>1</sup> at 25°. No. 1 and No. 2 are two completely different cells. No. 3 and No. 4 represent readings taken at the beginning and the end of a twenty-four hour run.

2. Cells,  $\text{Hg} \mid \text{HgCl}, \text{KCl} (c) + \text{KCl} (0.1 M) \mid \text{KCl} (0.1 M), \text{HgCl} \mid \text{Hg}$ .—It will not be necessary to go into detail in describing these measurements. Let it suffice to say that, if the solutions used in the calomel electrodes in these cells were allowed to stand three or four days at 25° before being introduced, measurements of the cells could be reproduced to within 0.05 of a millivolt. The object of these measurements is to determine the electromotive forces of the cells

Hence, it is necessary to eliminate the liquid potential from the cells in which ion-transference is taking place. To this end a formula, derived by MacInnes<sup>2</sup> from thermodynamic considerations of the electromotive forces of cells with and without transference, was used. This formula must hold throughout all ranges of concentration. It is

$$E_l = E_t (1 - 1/2n_c)$$

where  $E_l$  is the liquid potential,  $E_t$  the total electromotive force of the cell, and  $n_c$  the cation transference number. The equation of MacInnes gives the same results as would be obtained from the Nernst formula

$$E_l = (n_c - n_a)RT \ln c_1/c_2$$

if the correct activity values for the ions be substituted for the concentrations. Accurate data for the cation transference number of potassium chloride above 0.2 *M* were not available. The value<sup>3</sup> 0.495 was used throughout the complete range of concentrations employed.

These results are compiled in Table II.  $E_t$  is the electromotive forces of the cells with transference,  $E_l$  the liquid potential, and  $E_t + E_l$  the electromotive forces of the cells after the liquid potential has been elim-
